Successful intervention models for obesity prevention:
The role of healthy life styles

Vicente Martínez Vizcaíno¹,*, Jorge Cañete García-Prieto¹, Blanca Notario-Pacheco¹ and Mairena Sánchez-López¹,²

Abstract

Children obesity is considered a serious public health problem around the world. In Spain, the prevalence of overweight/obesity is reaching alarming figures, exceeding 35% of the children. Several hypotheses suggest that the energy balance model does not fit very well when analyzing the causes of the current obesity epidemic and, although genetics seems to explain up to 30% of the likelihood to become obese in infancy, has been suggested that genetics might be influenced by environment factors including vigorous physical activity (PA). Some recent systematic reviews indicate that there is enough evidence about the effectiveness of interventions to prevent obesity in children 6-12 years old; however, the heterogeneity of the effect, and the potential selection, information and publication biases that undermine the validity of these studies, thus their results should be interpreted with caution. In Spain, an extracurricular PA program of leisure-time (MOVI) has evidenced some effectiveness on reducing the adiposity and on improving the lipid profile in schoolchildren. To overcome some weakness of MOVI program, a second edition of this study was designed. The objectives of this review are twofold: 1) to analyze latest data of the obesity epidemic in Spain; and 2) to describe the main features of MOVI-2 program, and overall of the successful interventions to prevent children obesity.

Key words: Obesity. Interventions. Children. School. MOVI program.

Introduction

Children obesity remains a serious public health problem around the world¹. In Spain, current prevalence rates range from 35% to 42%.²³ Although recent studies have shown a leveling-off or even a decline in the prevalence of overweight/obesity in children in different countries of the world,⁴ in the period 2004-2010 prevalence of overweight in boys aged 8-11 years from Cuenca, Spain, increased from 21.6% to 28.0% and the percentage of body fat from 22.6% to 24.0%. In girls, however, the trend seems to have stabilized.²

In parallel to the growing trend in the overweight prevalence, during the last decade of the 20th century underweight prevalence was increasing in Spain, from

Determinants of the obesity epidemic in Spanish children

At the individual level, body fat accumulation results from an imbalance between energy intake and energy expenditure. If intake exceeds expenditure the excess of energy will be stored as fat. On the other hand, it has been estimated that genetics susceptibility explains about the 30% of the likelihood of child will develop obesity, although this is a polygenic inheritance strongly influenced by the interaction genes, environment and lifestyle.

However, at the population level non-genetic factors are the responsible for the frequency of obesity, including genetic, eating behavior patterns at an early age, activity/inactivity patterns, and other psychological, social and environmental factors. Nowadays, the relative importance of energy expenditure and intake in the development of the current obesity epidemic is a debatable issue. A recent review of studies addressing this question in different regions of the world concluded that in view of the great variability in the study designs, in the exposure and outcome measures used, and the wide population range in which the studies were based, the estimation of the importance of each one of these two factors, intake and energy expenditure, was not possible in children and teens.

In Spanish children, however, there are some considerations that worth to examine, and that leading us to suspect a greater importance of the decreasing of energy expenditure as determinant of the current obesity epidemic. First, data from both the AVENA study and the enKid study support the association between overweight and TV hours in Spanish children and adolescents. Furthermore, baseline measurement of an intervention study not yet published by our group show that children who are overweight or obese consume on average less calories/day than children with normal weight, and these normal weight children less than thinner children. After a first view of these data might be argued that children with overweight/obesity do less daily physical activity than less normal weight children, but when we controlled in multivariate models for cardiorespiratory fitness levels, a variable closely related to physical activity levels, these differences in energy intake by weight categories remain unchanged. These results are in accordance with that reported from other studies, and support the new hypothesis proposed by Gutin suggesting that vigorous physical activity at early ages would have a pivotal role in the of stem cells differentiation in bone and muscle tissues through stimulation by mechanical influences such as physical activity. If this theory were consolidated would have important implications in determine which is the best age range for implement preventive interventions, and which is the most appropriate type of activity for it. There are several hypotheses that do not support the energy balance model for explaining the childhood obesity epidemic, and even though no one doubt of the importance of genetics on predicting obesity, it has been suggested that genetics could be very strongly influenced by environmental factors including vigorous physical activity.

Efectividad de las intervenciones preventivas sobre obesidad infantil

A Cochrane systematic review aimed to evaluate the effectiveness of interventions for preventing obesity in children and adolescent concluded that there is enough evidence on the effectiveness of interventions to prevent obesity in children aged 6-12 years, although should be considered that the heterogeneity of the effect found in the studies, as well as the risk of design and publication biases, and therefore this results should be interpreted with caution. Furthermore this review concludes by recommending for future studies: 1) analyze the long-term results, 2) assess how those interventions that are effective can be maintained over time in a sustainable manner, 3) include economic evaluations, 4) potential damage reporting (i.e. eight reduction in thinner children, reduction of essential nutrients, etc.), 5) subgroup analysis by gender, location, race or socioeconomic status, 6) describe in detail the activities carried out in the intervention (to facilitate their applicability and transferability to other populations), and finally, 7) to focus on children 0-5 years.

A recent meta-analysis whose objective was to assess the efficacy of intervention programs on the body mass index (BMI) of children and adolescents, as well as explore the possible differences between the school and after-school intervention programs showed school or after school interventions had a similar effect. Considering that in Spanish context seems very complicated to propose legislative changes aimed to include interventions to tackle children obesity in the schools curricula, the implementation of interventions at recess or after school seems to be more feasible. The conclusions of a review that examines the systematic reviews and meta-analysis aimed to evaluate the effectiveness of programs addressing the prevention and control of childhood obesity indicates that information about the barriers and challenges encountered
when designing and implementing interventions in real life situations will provide important information on feasibility and sustainability, and identify if failure or modest success of the intervention was due to a problem with the intervention’s development, content or implementation.22

Most of the systematic reviews emphasize on the importance of taking into account the theoretical models of behavior’s changes in which the intervention is based.23 The usefulness of these models in the development of intervention strategies that affect multiple areas has been proven in several studies.24,25 One of the most commonly used is the socio-ecological model.26,27 This model distinguishes several levels on influence on behavior usually depicted as a graph with concentric circles (fig. 1). At the central level are represented the biological/genetic, physiological and sociocultural influences that make-up the individual’s identity. In the second circle are placed personal relationships, the environment close to the children; this micro-system consisted of relationships with parents, teachers, sibling, and friends. A third level of influence is known as exosystem, and includes physical and social environments that influence children’s behavior, but without interacting (neighborhood and its built environment, media, location of the school, working conditions of parents, etc.). Finally, the macro-system (fourth level) influences the child’s behavior; this macro-system includes traditions, social, culture, laws, history, etc., of the country where the child grows.

This paper review the characteristics of the most promising interventions.

Results

Table I shows characteristics of 12 effective school-based interventions on prevention obesity in children (6-12 years). All studies were randomized controlled trials, implemented in school area, and included as outcome BMI or prevalence of overweight/obesity.

Six studies were conducted in the United States, one in South America, one in Australia and four in different countries of the European Union (Spain, Switzerland, Germany and Sweden). Most of the studies were done in school (with modifications into curriculum),28-36 two studies were done in after school schedule (FitKid and MOV1),37-40 and one was done jointly in school and after school (STOPP).41 The duration of follow-up ranged from 3 months to four years; of these 12 studies, 2 studies had a follow-up period of 3 months, 5 studies between 8 months and one and a half year, and 6 studies more than one and a half year (two, three or four years). Seven of the interventions included increase in phys-
