MAGNETIC FIELDS AND POLARIZED EMISSION FROM SELECTED ENVIRONMENTS

R. H. Hildebrand[1] and J. E. Vaillancourt[2]

RESUMEN

Medidas de la emisión polarizada de las nubes moleculares han producido mapas de los campos magnéticos proyectados en el cielo. El espectro de polarización ha provisto evidencia de componentes múltiples en nubes en las cuales los granos de polvo a diferentes temperaturas tienen diferentes eficiencias de polarización. Con las mejoras en la resolución angular y con la selección adicional de longitudes de onda, está siendo posible hacer observaciones en entornos selectos tales como grumos densos, cúmulos de estrellas embebidas, y regiones de alta densidad en columna. Estas observaciones proveen modelos de nubes mejorados y también proveen de pruebas para los mecanismos de alineamiento de granos tales como el alineamiento por torcas radiativas. Medidas de la dispersión del campo, aplicadas a estudios de las intensidades de los campos o a la turbulencia, requieren resolución angular alta, y medidas precisas del ángulo de posición en muchos puntos. Las posibilidades para tales medidas, especialmente en el rango $\sim 50 - 200$ μm, serán realzadas enormemente cuando SOFIA esté equipada con un polarímetro de alto rendimiento en el lejano infrarrojo.

ABSTRACT

Measurements of polarized emission from molecular clouds have provided maps of magnetic fields as projected on the sky. The polarization spectrum has given evidence for multiple cloud components in which dust grains at different temperatures have different polarizing efficiencies. With improvements in angular resolution and with additional choices of wavelength, it is becoming possible to make observations in selected environments such as dense clumps, clusters of embedded stars, and regions of high column densities. These observations provide improved cloud models and also provide tests of grain alignment mechanisms such as alignment by radiative torques. Measurements of field dispersion, as applied to studies of field strengths or turbulence, require high angular resolution, and accurate position angle measurements at very many points. The possibilities for such measurements, especially in the range $\sim 50 - 200$ μm, will be greatly enhanced when SOFIA is equipped with a high-performance far-infrared polarimeter.

Key Words: ISM: dust, extinction — ISM: clouds — ISM: magnetic fields — polarization

1. INTRODUCTION

Well-known maps of starlight polarization (e.g., Mathewson & Ford 1970; Heiles 2000) have shown that the magnetic field in the tenuous environment along lines of sight to stars lies close to the Galactic plane. The few polarization vectors steeply inclined to the plane disappear if one selects only vectors toward distant stars (Figure 1).

By contrast, maps of polarized emission from individual molecular clouds at far-IR and submillimeter wavelengths show little or no relationship to the Galactic plane (Figure 1).

Within the clouds, one finds structure associated with processes such as expanding H II regions, differential rotation, or gravitational collapse. By combining flux maps, polarimetric maps, and ion and neutral molecular line width measurements, it is becoming possible to model 3-D magnetic field and mass distributions. A model for the molecular cloud DR 21 Main (Kirby 2009), indicates a collapsing core where the gravitational potential dominates over magnetic support within a radius of ~ 1 pc (Figure 2).

2. DUST ENVIRONMENTS

Characteristics of the environment that influence polarized emission include temperature structure, inclination to the line of sight, opacity, and exposure to radiation from embedded stars or the interstellar radiation field, all effects that bear on the polarization spectrum (Figure 3). A new result is a compar-

ison of degrees of polarization at 350 μm and 450 μm for measurements outside the central core of a cloud (Figures 4 and 5; Vaillancourt et al. 2008).

Our interpretation is that the dust exposed to radiation from embedded stars is warmer and better aligned (Hildebrand et al. 1999). The effect of

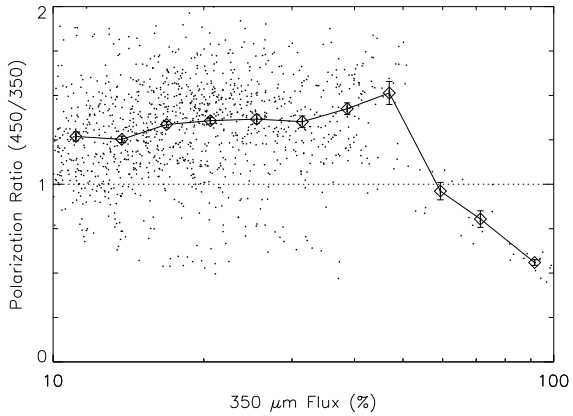

Fig. 4. Polarization ratio (450/350 μm) vs. the total 350 μm flux (Vaillancourt et al. 2008). Dots indicate individual measurements while diamonds represent an average over logarithmic bins of 350 μm flux. Error bars on the polarization ratio represent the standard deviation of the mean within each bin.

different dust components on the polarization spectrum is most obvious in high column density regions (flux > 50% of the peak flux in Figure 4) where both the warm aligned dust and cold nearly-unaligned dust both contribute significantly to the total submillimeter emission. The polarization ratio (450 μm/350 μm) changes as the relative emission contribution from the different components varies (Vaillancourt et al. 2008).

Theoretical arguments for grain alignment by radiative torques (Dolginov & Mytrophanov 1976; Draine & Weingartner 1996, 1997; Lazarian & Hoang

2007) have been confirmed by observations in the optical/near IR and FIR/SMM. Arce et al. (1998) have shown that the polarization of starlight from stars behind a molecular cloud, increases with increasing column density but only up to $A_V \approx 1$ where the interstellar radiation field does not penetrate. In some cases the polarization increases to higher A_V, but, as pointed out by Andersson & Potter (2007), what counts is not the column density toward the observer but rather the column density between the

dust and nearby sources of radiation. Whittet et al. (2008) have shown that the polarization of starlight increases in lines of sight near embedded stars. They have further shown that the growth of ice mantles on dust grains does not inhibit grain alignment. Hence the spin-up of grains by the formation and ejection of hydrogen molecules cannot be the dominant cause of alignment.

Additional tests of alignment by radiative torques should be feasible by comparisons of polarized emission with locations of embedded star clusters and surrounding warm dust emission seen in *Spitzer* maps at 3.6 μm (Figure 6). Finally, the importance of radiative torques may appear in SMM polarization maps along lines of sight through dense clumps indicated by molecular lines associated with high densities (Figure 7).

The development of valid models for the magnetic field structure of molecular clouds will require high resolution multi-wavelength polarimetry at thousand of points with small beams.

3. SUMMARY

1. The mean magnetic fields in molecular clouds do not lie along the Galactic plane.

2. Polarization maps of Orion and DR 21 Main show evidence of gravitational collapse. The maps of flux and polarization in DR 21 Main show that the gravitational potential should dominate over magnetic support within $\sim$ 1 pc ($\sim$ 1 arcmin) centered on the cloud core, a region enclosing $\sim 20,000$ solar masses.

3. The polarization spectrum of Orion, and presumably other giant molecular clouds, has a minimum near, and probably somewhat below, 350 μm.

4. The polarization spectrum depends on the temperatures, emissivities, and alignment efficiencies of dust grains in the various environments within the clouds.

5. A multi-wavelength photometer/polarimeter for SOFIA (Figure 8) will be uniquely suited to investigating the magnetic fields of molecular clouds (Dowell et al. 2003; Vaillancourt et al. 2007).

This work has been supported, in part, by NSF Grant AST 05-05124. Data for Figures 2, 3, 4, and 5 are from observations at the Caltech Submillimeter Observatory (CSO) with the polarimeter, SHARP (Li et al. 2008). SHARP has been supported by NSF Grants AST 02-41356, AST 05-05230, and AST 05-05124. The CSO is supported by NSF AST 05-40882. We would also like to thank Darren Dowell for providing Figures 1 and 6.
