SURFACE PROPERTIES OF NOVEL WOOD-BASED REINFORCED COMPOSITES MANUFACTURED FROM CRUSHED VENEERS AND PHENOLIC RESINS

Yuxiang Huang¹, Yue Qi¹, Yamei Zhang¹, Rongxian Zhu¹, Yahui Zhang^{1*}, Wenji Yu¹

ABSTRACT

This study was performed to determine the surface properties of novel wood-based reinforced composites made from poplar veneers and phenolic resins. The veneers with different thickness (1,8; 4; 6; 8 mm) were finely crushed and then were impregnated with phenolic resins to achieve different resin loading (12, 14, 18%). Finally, they were laminated or random paved to manufacture novel wood-based reinforced composites with different target densities (900-1100 kg/m³). With increased veneer thickness or resin content, the hardness of novel wood-based reinforced composites decreased and their roughness increased. The increase of density contributed to the increased hardness and decreased roughness. The surface wettability of novel wood-based reinforced composites appeared to be closely related to their surface roughness. There was a negative correlation between contact angle and roughness. The novel wood-based reinforced composites prepared by laminated mat formation showed higher hardness, lower roughness than those by random mat formation. Such data of surface properties can be applied to design the novel wood-based reinforced composites products with desired quality and provide basic information for further panel processing.

Keywords: Hardness, surface energy, surface roughness, surface wettability, wood composites.

INTRODUCTION

The scrimber manufacturing process has received considerable attention from researcher and industrialists in recent years. It is a kind of reconstituted wood product, which is manufactured from integrated parallel wood strips or veneers with addition of binders under application of temperature and pressure (He *et al.* 2016). Fast-growing species such as poplar (Li *et al.* 2016), *Eucalyptus*, bamboo (Chung and Wang 2017) and mulberry branches (Yu *et al.* 2015) are main raw materials for scrimber production. Compared with other wood composites such as particleboard and medium density fiberboard (MDF) (Candan *et al.* 2017), scrimber has excellent mechanical properties, which has the potential for structural applications in practical engineering.

The traditional scrimber manufacturing technique includes the whole log split into strands and this approach has a lot of drawbacks on account of the irregular shape of the wood units. Their uneven density and surface roughness lead to non-uniform adhesive and moisture distribution in the mats (Zhang *et al.* 2017). In our latest work, a process of veneers production, where the cut veneers were flattened and spit into strands by a pilot scale crushing machine, was implemented to manufacture novel wood-based reinforced composite (NWRCs) based on the traditional scrimber manufacturing process (Zhang *et al.* 2017). In the crushing machine, there are many special-shaped teeth on the round roller, so a series of dotted and/or linear shaped cracks formed in the veneers along the fiber direction. While maintaining high mechanical properties, the dimensional stability of this new product has been greatly improved. Surface properties of the substrate have significant effects on the quality of final products laminated with thin overlays. A large amount of research had been made to study the surface properties of untreated wood (Oberhofnerová *et al.* 2017), thermally compressed veneers (Aydin *et al.* 2005, Bekhata and Krystofiak 2016, Candan *et al.* 2010), overlaid particleboard and MDF (Büyüksarı 2013, Hiziroglu *et al.* 2004, Hiziroglu and Zarate 2007), wood polypropylene composites (Bledzki *et al.* 2010, Li 2014, Liu *et al.* 2016, Liu *et al.* 2010, Hutyrová *et al.* 2014). The techniques to evaluate the surface roughness and surface stability were also investigated in the literature.

However, there has been no study carried out to characterize the surface properties of scrimber, not to mention this novel composite manufactured from crushed veneers. Most of the studies focus on the mechanical properties of scrimber because it is relatively new as compared to other wood-based products. Therefore, the objective of this study is to evaluate the surface properties of novel WRCs to provide an initial data to the panel industry. In addition, investigation was also carried out to study the effects of veneer thickness, resin content, mat formation and density on the surface properties of the final wood composite product.

MATERIALS AND METHODS

Materials

Poplar wood (*Populus ssp.*) with the age of 4-5 years was obtained from Hebei province (65% of moisture content (MC), 30-35 of diameter and 380~420 kg/m³ of density). The PF resin was purchased from Guangdong Dynea Chemical Industry Co (molecular weight of 904-1070, 45% -solid content, 45 cps viscosity at 20°C obtained by rotating viscometer and pH of 9-10).

Preparation of finely crushed poplar veneers

After debarking, the round-wood with a length of 2 m was peeled into veneers with different thickness (1,8 mm, 4 mm, 6 mm and 8 mm). Afterwards, the veneers were cut into strips with a width of 200 mm, then the veneers entered the crushing machine (Figure 1) to obtain the fluffed poplar veneers with a series of uniform linear-shaped cracks along the grain direction. The crushed veneers were dried in a kiln to approximately 10% of MC.

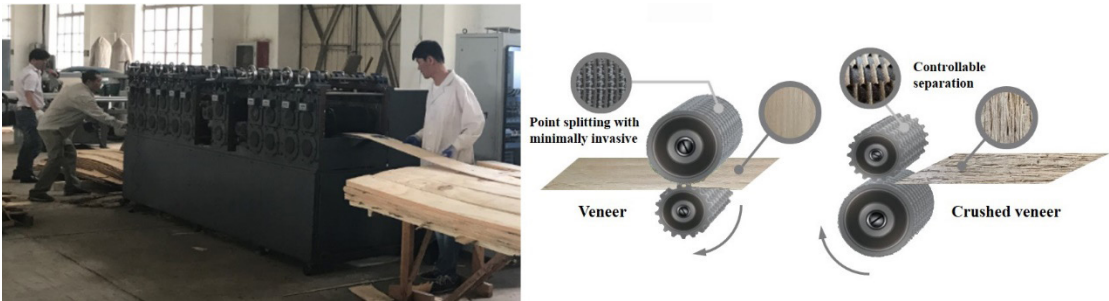

Figure 1: The photo of the crushing machine and its working principle.

Preparation of NWRCs

The crushed veneers were saturated in PF resin to achieve desired resin content (10%, 14% and 18%) and dried again to 12% MC. Cold-pressing and hot-curing were used in the forming process. The crushed veneers were weighed according to the desired density (900-1100 kg/m³) and then laminated or paved randomly along the grain direction in the mold. After being pressed in a cold pressing machine at room temperature, the veneers were placed in the air-circulated baking chamber at 120~130°C for 12 h to achieve the curing of PF resin. The obtained NWRCs with dimensions of 2000 mm (length) ×200 mm (width) ×150 mm (thickness) were conditioned in a chamber at 65% ±5% relative humidity (RH) at 20±2°C for 2 weeks before testing. Eight pieces of NWRC were manufactured under each condition, and five samples were cut from each NWRC. The conditions used for manufacturing NWRCs are listed in Table 1 in detail.

Table 1: Conditions used for manufacturing NWRCs.

Veneer thickness (mm)	Density (kg/m ³)	Mat formation	Resin content (%)
1,8	900	laminated	14
4,0	900	laminated	14
6,0	900	laminated	14
6,0	900	laminated	14
6,0	800	laminated	14
6,0	1000	laminated	14
6,0	1100	laminated	14
6,0	900	laminated	10
6,0	900	laminated	18
6,0	900	random	14

Measurement of hardness

The surface hardness of the NWRC samples (70×50×20 mm) was determined by XHR-150 plastic Rockwell hardness tester according to GB/T1941-2009. The hemispherical steel indenter with radius of 5,64 mm was used in the test. The indenter was pressed into the test surface until the depth was 5,64 mm. For the specimens which were easy to deform in the pressurization process, the depth of the head was allowed to be reduced to 2,82 mm.

Determination of surface roughness

The surface roughness of the NWRC samples was measured with a TIME 3230 surface roughometer. Specimens of 80×20 mm squares were cut and then sanded with 240-grit sand paper for 1 min. A Gaussian filter with a cutoff wavelength of 0,8 mm was used to transform the data. Two roughness parameters, average roughness (R_a), mean peak-to-valley height (R_z), were used to evaluate surface roughness of the samples. Three specimens were sampled for each group with the same density, and four random measurements of surface roughness were taken per specimen.

Surface morphology of NWRCs

The surface morphology of NWRCs were observed with an optical microscope (VHX-1000E), a new ultra-depth 3-dimensional microscopy system (UDM), made by KEYENCE.

Measurement of contact angle and calculation of extension and penetration rate parameter

Three liquids (distilled water, formamide, and diiodomethane), which may be used in coating adhesion during the process of surface finishing, were chosen to determine the wettability of NWRCs. The NWRC samples were cut into small blocks with a size of 80×42×6 mm, and then, their lateral surfaces were sanded with 240-grit sand paper. The wetting behavior was determined on the tangential section of the samples by the sessile drop method with an OCA20 contact angle measuring instrument (Dataphysics, Germany). Five tests were performed on each specimen, and two replicates were carried out for each group. An automatic micro syringe was used to dispense drops of approximately 4 μ L test liquid. The contact angle of droplet on each sample was measured at intervals of 1 s after the liquid droplet fell down on the sample surface.

In the process of liquid wetting, the contact angle gradually decreases with the time attributable to the extension and penetration of the liquid, and finally trends to relative balance. For an ideal solid-liquid system, the speed of extension and penetration depends on the contact angle at a given time (Shi and Gardner 2001):

$$\frac{d\theta}{dt} = -K\theta \tag{1}$$

where θ_e is the constant of the change of contact angle.

With the prolongation of time, the extension and penetration rate of the contact angle is slowed down, and the change speed of the contact angle decreases, and finally is close to zero. Thus, a limit is added to Equation 1.

$$\frac{d\theta}{dt} = -K\theta \left(1 - \frac{\theta_i - \theta}{\theta_i - \theta_e} \right) \quad (2)$$

Where θ_i is the initial contact angle and θ_e is the equilibrium contact angle. In the Equation 2, K represents the rate constant of the reduction of relative contact angle. Change the form of the Equation 2.

$$\frac{d\theta}{dt} = K\theta \left(\frac{\theta_e - \theta}{\theta_i - \theta_e} \right) \quad (3)$$

After rearranging Equation 3, the Equation 4 is obtained.

$$\theta = \frac{\theta_i \theta_e}{\theta_i + (\theta_e - \theta_i) \exp \left[K \left(\frac{\theta_e}{\theta_e - \theta_i} \right) t \right]} \quad (4)$$

The change of contact angle is caused by the extension and penetration of the liquid on the surface of the solid. Therefore, the K value can also be considered as the diffusion rate parameter of the liquid on the surface of the solid, which is used to characterize the extension and penetration rate of a liquid on a solid surface. The higher the K value, the more rapidly the contact angle reaches equilibrium and the faster the liquid penetrates and spreads, and vice versa. The K value of a particular liquid-solid system can be determined by curve-fitting the experimental data to Equation 4 using a nonlinear method (Huang *et al.* 2012).

Calculation of surface free energy

The surface free energy of samples with various densities was also calculated by the Lifshitz-van der Waals/acid-base (LW-AB) approach (Oss 1993, Gindl *et al.* 2001, Wålinder 2002, Santos and Goncalvez 2016). According to this approach, the surface free energy is a sum of Lifshitz-van der Waals component (γ^LW) and the acid-base (γ^{AB}) component. The mathematical approach for the solid/liquid interfacial tension is given by Equation 5:

$$\gamma_L (1 + \cos \theta) = 2 \left(\sqrt{\gamma_S^{LW} \gamma_L^{LW}} + \sqrt{\gamma_S^+ \gamma_L^-} + \sqrt{\gamma_S^- \gamma_L^+} \right) \quad (5)$$

where θ is the contact angle, and the subscripts S and L denote solid and liquid phases, respectively. γ^+ denotes electron-accepting component, and γ^- is electron-donating component.

RESULTS AND DISCUSSION

Hardness of NWRCs

Hardness reflects the resistance of a material against indentation. Figure 2a shows the effect of veneer thickness on the hardness of NWRCs. In the case of density of 900 kg/m³ as well as resin content of 14%, the hardness of NWRCs gradually decreased with the increase in the thickness of veneers. The maximum decline (11,4%) appeared when the veneer thickness increased from 6 mm to 8 mm. The thicker the veneer, the more severe the cell wall collapsed during the fluffing process. Thus, the hardness of the product decreased when the veneers were manufactured into NWRCs.

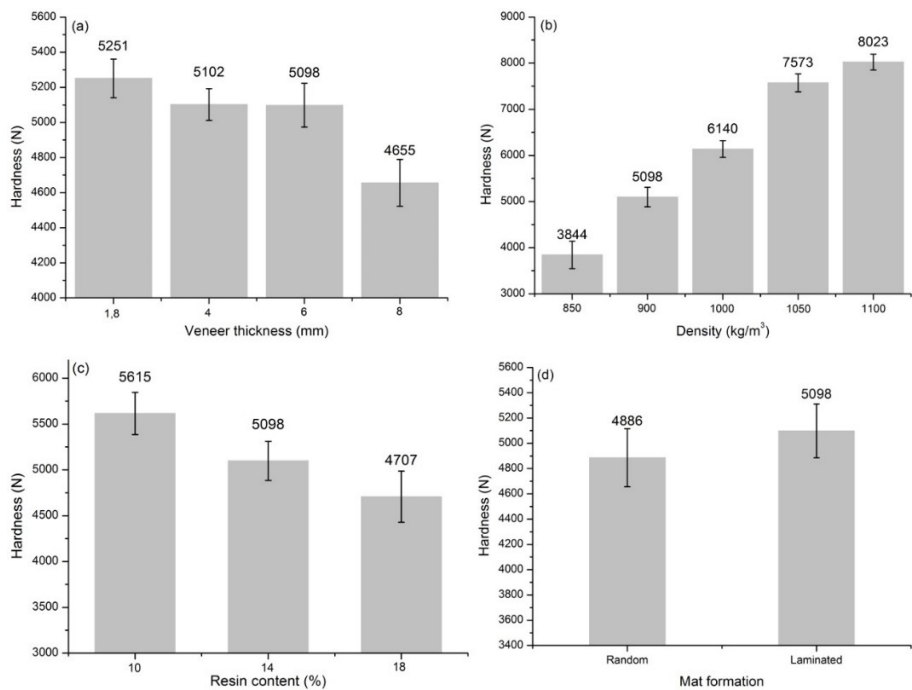

Figure 2: The influence of veneer thickness (a), density (b), resin content (c) and mat formation (d) on the hardness of NWRCs

In the case of 6-mm-thick veneers as well as resin content of 14%, the hardness of NWRCs increased as density increased (Figure 2b). This was attributable to the higher densification on the face layers of samples resulting in harder surface. Similar results were observed by several researchers (Fang *et al.* 2012, Unsal and Candan 2008). Fang *et al.* (2012) found that Brinell hardness of densified veneers was approximately two or three times that of control for both aspen and hybrid poplar. Unsal and Candan (2008) stated that the increase of hardness of solid pine wood with increasing press pressure and temperature could be attributed to the increase in density of the specimens. As the density increased from 850 kg/cm³ g cm⁻³ to 1050 kg/cm³, the hardness of the NWRCs nearly doubled. While the density exceeded 1050 kg/cm³, the increase in hardness of the NWRCs was not obvious. The NWRCs with density of 1100 kg/cm³ had the greatest hardness with value of 8023 N.

Under the process conditions of 6-mm-thick veneers and density of 900 kg/cm³, the hardness of NWRCs prepared by laminated mat formation gradually decreased with an increase in resin content (Figure 2c). Compared with the NWRCs with resin content of 10%, those with resin content of 18% had a 16,2% decrease in hardness. However, only a slight decrease of 4,2% was found from the hardness of NWRCs prepared by parallel mat formation to that by random mat formation (Figure 2d), indicating that mat formation seemed to have no significant effect on the hardness of NWRCs. In the scope of the design of this study, the hardness of NWRCs fell in the region of 4000-9000 N. The lowest hardness was equivalent to that of cherry, walnut and elm, while the highest hardness was comparable to sandalwood (*Santalum album*).

Roughness of NWRCs

Figure 3a shows average values of roughness parameters obtained from the surfaces of NWRCs at different veneer thickness levels. The smoothest surface was observed in NWRCs of 2 mm-thick veneers ($R_a=2,68\text{ }\mu\text{m}$). The original surface quality of NWRCs were better than that of *Pterocarya fraxinifolia* LVL from 2,3-mm-thick rotary peeled veneers ($R_a=6,83\text{ }\mu\text{m}$) (Gungor *et al.* 2006) and that of *Sorbus aucuparia* L. LVL from 1,6-mm-thick veneers ($R_a=5,13\text{ }\mu\text{m}$) (Kol *et al.* 2009). The R_a value of the NWRCs decreased with increasing veneer thickness. As for LVL and plywood, the veneer thickness only had significant effects on the mechanical properties and dimensional stability of the panels (Melo 2014), while seemingly it had no effects on the surface quality. However, during the manufacturing process of NWRCs, the surface quality of the veneers was changed after fluffing. There were more cracks on the surface of the thick veneers which bore more pressure during the crushing process, thereby affecting the surface quality of the final products.

As density increased from 800 kg/cm^3 to 1050 kg/cm^3 , the R_a value of NWRCs gradually decreased (Figure 3b). The increased density resulted in the enhancement of dense effect of the NWRCs, thereby leading to a more compact surface. Similar result was found by Akbulut and Koç (2004) in the study of MDF, of which increasing the panel density decreased the roughness of the profiled areas.

On the contrary, there was a positive correlation between the resin content and the surface roughness, where the R_a value of NWRCs increased with increasing the resin content (Figure 3c). The increase in the resin content contributed to a decrease in the wood content of the composite, which contributed to the increased surface roughness. The R_a values of NWRCs manufactured by random mat formation are higher than those of the samples by parallel mat formation (Figure 3d). This rougher surface could be ascribed to the tiny cavity formed by the folding and stacking of the material during the pressing process.

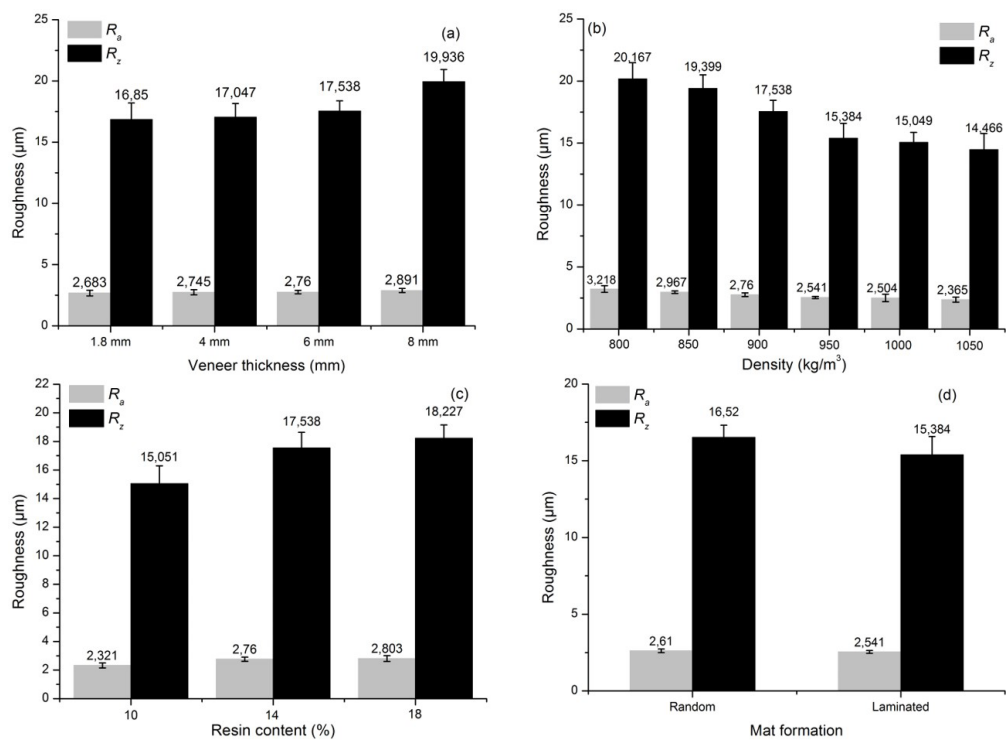

Figure 3: The influence of veneer thickness (a), density (b), resin content (c) and mat formation (d) on the surface roughness of NWRCs.

The R_z parameter of NWRCs had similar trends to the R_a values. The R_z value of NWRCs also increased with increasing the veneer thickness. The increase (13,7%) was found to be significant when the thickness exceeded 6 mm. Decreasing the density or increasing the resin content also resulted in the increase of the R_z value.

Under the observation of the ultra-depth microscope, the surface appearance and the line roughness are consistent with the above surface roughness results (Figure 4a, Figure 4b, Figure 4c, Figure 4d). In addition, in the case of different resin content, high resin content can form a more uniform package for the material (Figure 4e).

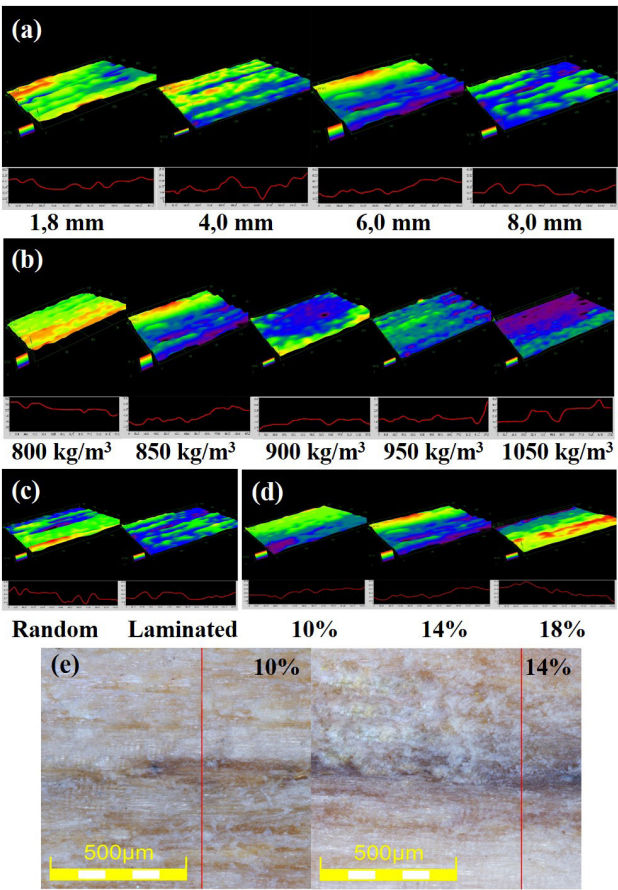

Figure 4: The influence of veneer thickness (a), density (b), mat formation (c) and resin content (d) on the surface morphology and line roughness of NWRCs and surface packages of NWRCs with different resin content (e).

Surface wettability of NWRCs

The initial stage of liquid droplets formed on the surface of the NWRCs could be considered as stable. After a short period of the thermodynamic stability, the droplets are affected by the surrounding natural environment. In the macroscopic view, the contact angle changed with time (Figure 5). With the increase in the thickness of the veneers, the initial contact angles of NWRCs gradually decreased, and the *K* values increased with rising the thickness of the veneers.

Figure 5: Dynamic contact angles by three different liquids as a function of a time for the NWRCs with different veneer thickness.

The distilled water showed the largest initial contact angle on the surface of the material, while formamide showed the smallest one. On the contrary, the K value for formamide was the highest, followed by the distilled water, the last was diiodomethane. Similar results were found by several researchers (Huang *et al.* 2012, Stehr *et al.* 2001). Huang *et al.* (2012) found that formamide has the highest K values compared with those of water and ethylene glycol. Stehr *et al.* (2001) stated that formamide is a strong hydrogen-bonding liquid that radically decreases the interfacial free energy at the liquid-solid interface through acid base interactions, thereby increasing the spreading and penetration rate. The change of surface contact angle is mainly caused by the acid-base (γ^{AB}) component of wetting liquid. Further, it is affected by the electron-donating component of the liquid (γ_L^-). The greater the γ_L^- value, the greater the change of contact angle, and the better the permeability. The influence of the veneer thickness on the contact angle of WRCs was mainly caused by the roughness, and the roughness of the surface geometry was the main factor to determine the surface wettability. According to the Wenzel theoretical model, for a given surface, the roughness factor of the surface has amplification effect on the surface wettability. Increasing the roughness would make the hydrophilic surface more hydrophilic, and the hydrophobic surface more hydrophobic. Therefore, the results of this study were also fully consistent with the Wenzel theory model. The increase of the veneer thickness led to the increase of the roughness, which improved the surface wettability of the material and reduced the contact angle.

Figure 6 shows the dynamic contact angles by three different liquids as a function of a time for the NWRCs with different densities. The initial contact angle of NWRC was positively related to its density. The distilled water still showed the largest initial contact angle on the material surface, while formamide showed the smallest. The increase of contact angle could be attributed to the decrease of the surface roughness with rising the density.

Figure 6: Dynamic contact angles by three different liquids as a function of a time for the NWRCs with different densities.

The change of contact angle with resin content or mat formation was closely related to the change of the roughness (Figure 7). The increase of the resin content resulted in the increase of surface roughness, thus reducing the contact angle. The NWRCs manufactured by random mat formation has rougher surface, correspondingly their contact angles are higher than the samples by parallel mat formation.

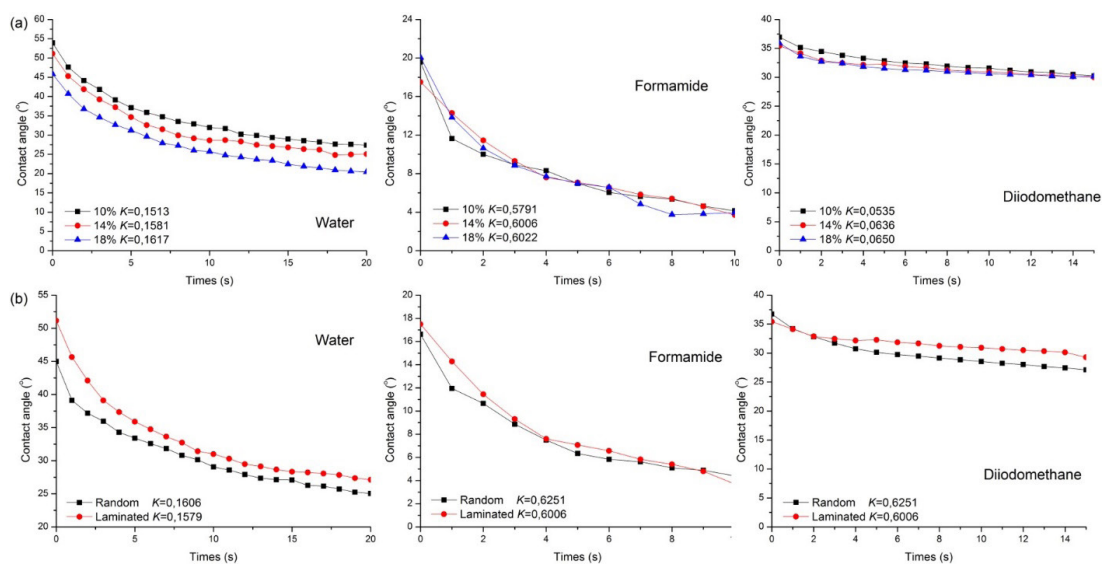

Figure 7: Dynamic contact angles by three different liquids as a function of a time for NWRCs with different resin content (a) and mat formation (b).

Surface free energy

As seen from Table 2, the surface free energy of the material (γ_s^T) was composed of Lifshitz van der Waals force (γ_s^{LW}) and acid base force (γ^{AB}), where γ_s^{LW} occupied the main part. The size of the acid energy factor (γ^+) and the basic energy factor (γ^-) indicated the electronic granting ability and proton granting ability, respectively. With the increase of the veneer thickness, the surface free energy of NWRCs gradually increased attributable to the increase of γ_s^{LW} . As the density increases, the surface free energy of NWRCs also increased, whereas γ_s^{LW} gradually decreased. On the contrary, γ^{AB} increased, suggesting the increase of the surface polarity. With the increase of resin content, the surface free energy of NWRCs decreased slightly. The difference of the surface free energy was caused by γ^{AB} .

The increase of resin content made the material to be evenly wrapped, resulting in a blunt surface. This reduced the surface polarity, which led to a decrease in the acid-base properties of the surface. The surface free energy of NWRCs prepared by random mat formation was slightly higher than that by parallel mat formation.

Table 2: Surface tension components of NWRCs from acid-base model.

Parameters	Veneer thickness (mm)				Density (g cm ⁻³)						Resin content			Mat formation	
	1,8	4	6	8	0,8	0,85	0,9	0,95	1	1,05	10%	14%	18%	Laminated	Random

CONCLUSIONS

This study evaluated surface properties including hardness, roughness, wettability and surface energy of novel wood-based reinforced composites (NWRCs) from crushed poplar veneers under different technical conditions. Our finding suggested that increasing the density and decreasing the veneer thickness or resin content could improve the hardness of NWRCs and reduce their surface roughness. The surface wettability of NWRCs was closely related to their surface roughness. Such data can be applied for practical use in manufacturing NWRCs with controlled quality.
