ABSTRACT

The present research aimed to characterize some biochemical responses of *Coffea canephora* (clones 02 and 153) and *C. arabica* (Catucaí IPR 102) genotypes subjected to low positive temperatures, helping to elucidate the mechanisms involved in cold tolerance. For that, one year old plants were subjected successively to 1) a temperature decrease (0.5°C a day) from 25/20°C to 13/8°C (acclimation period), 2) a three day chilling cycle (3x13/4°C) and to 3) a recovery period of 14 days (25/20°C). In Catucaí (less cold sensitive when compared to clone 02) there was an increased activity in the respiratory enzymes malate dehydrogenase and pyruvate kinase. Furthermore, Catucaí showed significant increases along the cold imposition and the higher absolute values after chilling exposure of the soluble sugars (sucrose, glucose, fructose, raffinose, arabinose and mannitol) that are frequently involved in osmoregulation and membrane stabilization/protection. The analysis of respiratory enzymes and of soluble sugar balance may give valuable information about the cold acclimation/tolerance mechanisms, contributing to a correct selection and breeding of *Coffea sp.* genotypes.

Key words: coffee tree, *Coffea sp.*, sucrose, enzymes, cold stress.

RESUMO

A pesquisa teve por objetivo caracterizar respostas bioquímicas de genótipos de *Coffea canephora* (clones 02 and 153) e *C. arabica* (Catucaí IPR 102) submetidos a baixas temperaturas positivas, ajudando a elucidar os mecanismos envolvidos na tolerância ao frio. Plantas com um ano de idade foram submetidas sucessivamente a 1) decréscimo da temperatura (0,5°C por dia) desde 25/20°C até 13/8°C (período

de aclimatização), 2) um ciclo de três dias a 13/4°C e 3) 14 dias de recuperação (25/20°C). Em Catucaí, genótipo menos sensível ao frio quando comparado com o clone 02, observou-se um aumento das atividades das enzimas malato desidrogenase e piruvato cinase, relacionadas com a respiração. Nesse genótipo, os níveis de açúcares solúveis sacarose, glucose, frutose, rafinose, arabinose e manitol (frequentemente envolvidos em processos de regulação osmótica e estabilização/proteção de membranas) aumentam significativamente durante a imposição de baixas temperaturas, mostrando ainda os valores absolutos mais elevados depois de exposição a 4°C. Portanto, a análise de enzimas respiratórias e do balanço de açúcares solúveis pode fornecer informação importante sobre mecanismos de aclimatização/tolerância ao frio, contribuindo para seleção e melhoramento de genótipos de *Coffea sp.*

Palavras-chave: cafeeiro, *Coffea sp.*, sacarose, enzima, estresse de frio.

INTRODUCTION

The genus *Coffea* comprehends at least 103 species, with commercial relevance for *C. arabica* and *C. canephora* (DAVIS et al., 2006). World's coffee production in the last years has being of more than 110 million sacks, produced essentially in developing countries (ICO, 2009). Brazil is the world's biggest coffee producer and exporter, and has in this culture an important source of incomes, employment and local development in the producing or processing regions.

Exposure to non-freezing temperature has a depressing effect on growth, photosynthetic performance and yield. Besides that, low temperatures can damage root system, with a consequent leaf death. Plants have mechanisms of cold acclimation that promote quantitative and qualitative modifications of membrane lipids, increased activity of antioxidant enzymes and increased ability to dissipate excess energy. In fact, the existence of different acclimation abilities within the *Coffea* genus seems to be related to the tolerance of the photosynthetic apparatus in face of oxidative stress conditions (RAMALHO et al., 2003). The presence of these mechanisms is essential for the implementation and maintenance of plant species in a region, influencing plant performance and agricultural practices, as well as the economical viability of the crop. Thus, this knowledge is important for the selection and management of the genus *Coffea* (PRAXEDES et al., 2006).

Growers and researchers believe that Conilon cultivation may be an alternative in such areas, once this species has a higher tolerance to biotic and abiotic stress than *Arabic coffee*, despite its higher susceptibility to low temperatures (RAMALHO et al., 2003). In this way, the objective of the present research was to contribute to the characterization of physiological and biochemical responses of *Coffea canephora* and *C. arabica* genotypes subjected to low positive temperatures, helping to elucidate the mechanisms involved in cold tolerance/sensitivity.

MATERIAL AND METHODS

One year old plants of *Coffea canephora* cv. 'Conilon': clone 02 (early ripening) and 153 (late ripening), and *C. arabica* cv. 'Catucaí IPR 102' were used for the experiments. Coffee plants were grown in pots containing 3L of substrate (soil:sand, 4:1 and organic plus chemical nutrients) in a greenhouse at the Center of Vegetal Ecophysiology, Biochemistry and Biotechnology from the Tropical Research Institute in Oeiras, Portugal.

Plants were transferred to growing chambers (*walkin* type, Fitoclima 1000 EHHF) with 700-900 $\mu\text{mol m}^{-2} \text{s}^{-1}$ of irradiance, CO_2 concentration of 380 $\mu\text{L L}^{-1}$, 70% relative humidity, 12h photoperiod and 25/20°C (day/night) temperatures for a period of 15 days, in order to promote plant acclimation to this environmental conditions set as control. After that, plants were submitted to a gradual temperature reduction (0.5°C a day), from 25/20°C to 13/8°C, during a 24 days period, in order to allow a gradual expression of the acclimating potential to low temperatures. After this period, plants were subjected to three consecutive

chilling cycles at 4°C at night and in the first four hours of the next day and 13°C during day time (3x13/4°C), followed by a recovery period by raising the temperature to 20/15°C in the first day and to 25/20°C the following 13 days.

All analyses were performed in recently mature leaves under, at least, six conditions: 1) 25/20°C (control); 2) 18/13°C (half of the acclimation period); 3) 13/8°C (end of the acclimation period); 4) 3x13/4°C (after three cycles of low positive temperature); 5) at 25/20°C, seven and 14 days after the end of the low temperature exposure. Leaf material was collected after 2-2:30 minutes of illumination, from six to eight plants of each genotype, which were immediately frozen in liquid nitrogen and placed at -80°C until analysis.

For measuring the activity of respiration key enzymes, four replicates of each samples (2cm²) were homogenized in a cooled mortar using 100mg PVPP (antioxidant) and 1mL extraction buffer 100mM Tris-HCl (pH 8), containing 10mM MgCl₂, 10mM NaHCO₃, 10mM β -mercaptoethanol, 2mM DTT, 1% (v/v) Triton X-100, "complete-protease inhibitor cocktail" 2% (v/v) and 10% (v/v) glycerol. Extracts were centrifuged (16,000g, 20min, 4°C) and used for determination of enzymatic activity, based on NADH oxidation at 340nm and 21°C, in a spectrophotometer UV-Vis (Bio-Rad Smart - 3.000) (MAROCO et al., 1999). Enzymatic activity was calculated according to the following formula: Activity = [$\mu\text{mol NADH m}^{-2} \text{s}^{-1}$ = OD/seconds x (1/6.22) x (total volume/sample volume)/fresh weight]; Where OD corresponds to the optical density obtained and 6.22 is the absorptive coefficient (ϵ_{NADH}).

For determination of the enzyme pyruvate kinase (PK) activity, de-ionized water was used in buffer 100mM Tris-HCl (pH 8), containing 10mM MgCl₂, 0.2mM NADH, 1mM fructose-1,6-phosphate, 45mM ADP, 6.3 U mL⁻¹ lactate dehydrogenase and 40 μL of the over floating. Reaction was initiated with the addition of 1mM phosphoenolpyruvate (PEP) in 1mL final volume. For the determination of the malate dehydrogenase (MDH) activity, a buffer 50mM Tris-HCl (pH 8), containing 0.1mM NADH and 20 μL extract, was used. Reaction was initiated with addition of 0.4mM oxalacetate, in a final volume of 1mL (LÓPEZ-MILLÁN et al., 2000).

For soluble sugar determinations the analysis procedure was based on DAMESIN & LELARGE (2003), after minor optimization modifications for coffee. Approximately 100mg of leaf material was homogenized in 2mL pure cold water and 50mg PVPP, left with agitation (20min, 4°C) and centrifuged (12,000g, 5min, 4°C). The supernatant was successively submitted to 100°C for 3min in a water bath, placed in ice for 6min, centrifuged (12,000g, 15min, 4°C) and

filtered (nylon filter, 0.45µm), before HPLC analysis. Aliquots of 80µL were injected in an HPLC (Waters, USA) equipped with a refractometric detector (Waters 2414) and Sugar-Parkl column (Waters 300x6.5mm) in oven at 90°C. Pure water, containing EDTA-Ca at 50mg L⁻¹, was used as eluent, with 0.5mL min⁻¹ isocratic flow, for 22min. Sugar identification and quantification was performed using standards of known concentration.

Statistical analyses of data followed a completely randomized design, with four replicates. A two-way ANOVA ($P < 0.05$) was applied to evaluate differences between temperatures and between genotypes, followed by a Tukey test for mean comparison (95% confidence level).

RESULTS AND DISCUSSION

It is known that the maintenance of respiratory metabolism is important once it allows energy production, redox capability and the synthesis of metabolic intermediaries that make possible metabolism in general, and processes of reparation in particular, under low temperature conditions. In cold-sensitive plants, respiration is strongly affected due to the inhibition of several enzymes, which provokes an exponential decline of respiratory rates with decreasing temperatures (LARCHER, 1981). Photosynthesis is strongly suppressed in coffee leaves under temperatures below 18/13°C (RAMALHO et al., 2003) what would limit the ATP supply to cellular metabolism. However, the need of ATP for cellular processes may induce the increase of the respiratory rate, as observed by DAY & LAMBERS (1983). In fact, the enzymatic activity of MDH and PK increased for temperatures below 18/13°C (Table 1), except in clone 153 for PK. Thus, considering that these enzymes are involved in glycolysis of the respiratory process, such significant

activity increases during the exposure to low temperatures and in the following recovery period would allow higher energy availability for cellular metabolic processes, particularly in Catucaí and clone 02. However, differently from Catucaí, such increase in respiration did not mean a higher cold tolerance in clone 02. This suggests that, at least for some plants, such increased respiratory activity is not enough and could not be directly correlated with cold tolerance, as reported in *Zea mays* subjected to 5°C (RIBAS-CARBO et al., 2000).

Furthermore, the limitation of Pi availability in the chloroplast could provoke a reduction of photosynthesis in plants subjected to low temperatures, once a reduction in the enzymatic activity regulating sucrose content may occur, reducing sucrose concentration and increasing phosphate-sugars (SAGE, 1994). Such sucrose decrease was evident in the Conilon clones (Table 2), what could result from sucrose-P synthase (SPS) inhibition. In fact, the inability of fully activate SPS is amongst the factors that contributes to a poor photosynthetic performance and a higher cold sensitivity (STRAND et al., 1999). However, low Pi availability was reported to provoke decreases in PK and MDH (KIHARA et al., 2003), what is not the case in coffee leaves, thus suggesting that Pi levels were not limiting.

Carbohydrates are a major category of compatible solutes that include hexoses (mostly fructose and glucose), disaccharides (sucrose, trehalose), sugar alcohols (inositol, mannitol) and complex sugars (raffinose and stachyose), all of which accumulate during stress (MORSY et al., 2007). The contents of the major monosaccharides displayed strong changes upon cold exposure and in the period following the end of the stress (Table 2). There was an increment in the glucose and fructose contents at 13/8°C and 3x13/4°C in Catucaí and clone 02, as it was

Table 1 - Enzymatic activity ($\mu\text{mol s}^{-1} \text{g}^{-1}$ of dry matter) in leaves collected after two hours of illumination, in different genotypes of *Coffea* sp. submitted to a gradual decrease of temperature (25/20°C until 13/8°C) during 24 days, three cycles at temperature of 13/4°C (3x13/4 °C) and latter periods of recovery (Rec) at 25/20 °C (at the end of seven and 14 days).

observed in *C. dewevrei* (RAMALHO et al., 2003). This was not the case in clone 153, similarly to what has been observed in *C. canephora* cv. Apoatã and *C. arabica* cv. Icatu by RAMALHO et al. (2003). These data clearly shows different impacts of cold amongst genotypes. The increase of these hexoses may reflect a lower use by the cellular metabolism, but in case of clone 02 a sucrose synthesis inhibition (by an eventual inhibition of SPS), would also be involved once this sugar was consistently reduced. In Catucaí, the slight increase of sucrose concomitantly to the increase in glucose and fructose levels upon cold exposure, (the latter mostly resulting from a lower utilization rather than an increase of production, since photosynthesis was negligible at 13/8°C and upon chilling) could indicate a higher tolerance to cold. In fact, the maintenance or increase in sucrose content was shown to provide higher tolerance to plants under cold (PALONEN et al., 2008) and drought (PRAXEDES et al., 2006) stresses.

In clone 153, glucose and fructose contents were always smaller than in the other genotypes and

were maintained under cold treatment, concomitantly with a sucrose decrease. Similar changes of sucrose content were also observed in water deficit sensitive clones of *C. canephora* cv. Conilon (PRAXEDES et al., 2006). To such sucrose reduction may have accounted the maintenance of sucrose translocation to other plant tissues, its degradation to monosaccharides, that in turn could be used in respiration (due to the increase of MDH and PK activities), or a reduced synthesis, once SPS could be sensitive to low temperatures (ALLEN & ORT, 2001) and to water deficit (PRAXEDES et al., 2006).

Until the end of the experiment, 14 days after the end of chilling stress, the sucrose, glucose and fructose contents were quite different to their control values, suggesting incomplete recoveries for all genotypes, but in Catucaí a tendency to reach control values is clearer, especially regarding the hexoses.

The content of raffinose, a trisaccharide of galactose, fructose, and glucose, only increased significantly with the decrease in temperature in Catucaí (Table 2), approaching to control values after chilling exposure. This sugar may contribute to increased

tolerance to low temperature, since it was associated to membrane stabilization. In fact, raffinose increase was reported in *Oryza sativa* (MORSY et al., 2007) cold tolerant plants when compared to the sensitive ones, as well as during the cold acclimation process (PALONEN et al., 2008).

Stachyose, a tetrasaccharide with two galactose, one glucose and one fructose molecules, increased gradually in all coffee genotypes under low temperatures, as also noted by TAPERNOUX-LÜTHI et al. (2004) in other plants. Such increases of stachyose and raffinose might be involved in the acclimation process to low temperatures, as suggested for *Lonicera caerulea* L. (IMANISHI et al., 1998). In this way, the highest values of both sugars in Catucaí at the end of the acclimation period (13/8°C) would confer a better protection for the chilling exposure. Clone 153 presented also high contents of stachyose at 13/8°C and onwards, while clone 02 presented the higher value of raffinose by the 7th day of recovery.

Concerning arabinose, a monosaccharide pentose sugar, increased levels were found following the cold treatment in clone 02 and Catucaí, doubling its values under chilling. The latter showed also systematically higher values during the experimental period. Arabinose (as well as hidroxiprolina) is an important component of the glycoproteins that has an important structural role in the cell wall, being particularly necessary in acclimation conditions to low temperatures to maintain cell wall extensibility. Hence, an increase in arabinose may indicate an increase in extensine, as suggested by WEISER et al. (1990).

Mannitol, an hexose sugar alcohol, also increased in all studied genotypes with the reduction of temperature (Table 2), with Catucaí showing the highest percentage and absolute values changes at 13/8°C and 3x13/4°C. It must be noted that mannitol values presented in the coffee genotypes are quite high, particularly in Catucaí where it reached 70% of the sucrose value after the chilling exposure. In vascular plants, mannitol is synthesized from mannose-6-phosphate through the action of an NADPH mannose-6-phosphate reductase (M-6-PR) that catalyzes the conversion of mannose-6-phosphate to mannitol-1-phosphate, followed by dephosphorylation. Mannitol synthesis may occur simultaneously with either sucrose or raffinose synthesis (STOOP et al., 1996), but in Catucaí all 3 sugars increased simultaneously. Some advantages have been suggested for plants that use mannitol as a photoassimilate and phloem-translocated carbohydrate, due to a higher carbon use efficiency of mannitol metabolism that has a higher net ATP yield than the catabolism of an equal amount of sucrose. Furthermore, mannitol-producing plants exhibit a high degree of salt tolerance, due to its role of

osmoregulator and osmoprotectant. Thus, under dehydration (which is often associated to cold stress) such plants will display a better tolerance by maintaining mannitol biosynthetic capability, whereas photosynthetic sucrose synthesis is largely suppressed (STOOP et al., 1996).

Therefore, Catucaí showed the higher absolute values and significant increases after the three cycles at 13/4°C (except for stachyose after chilling exposure) of the soluble sugars related with osmotic regulation and membrane stabilization and protection (MORSY et al., 2007), what may confer a higher cold acclimation ability, since the increase of cold tolerance could be associated to increases in the concentration of monosaccharides and sucrose (UEMURA & STEPONKUS, 2003). This could be associated to the lower cold impact on photosynthesis observed in this genotype and therefore more efficient acclimation mechanisms to chilling (PALONEN et al., 2008).

The ability of response to environmental changes is a requisite for plant survival, with enzymatic and sugar content alterations in the plant tissues being important indicators of a species acclimation capacity (LÓPEZ-MILLÁN et al., 2000). In fact, among other responses, the ability to maintain production and consumption of carbohydrates, as well as stabilization of its levels, are very important for cold tolerance (ALLEN & ORT, 2001).

CONCLUSION

Coffee genotypes under study showed sensibility to low temperatures, but with different tolerance and recovering abilities. In this way, the better ability to cope with cold stress of Catucaí IPR 102, when comparing to Conilon clones (especially with clone 02), may be associated, among other factors, to higher activities of MDH and PK respiratory related enzymes, what agrees with the hypothesis that the maintenance of respiratory activity is an important component of cold acclimation.

‘Catucaí IPR 102’ showed significant increases along the cold imposition and the higher absolute values after chilling exposure of all soluble sugars under study (except for stachyose). Those molecules are frequently involved in osmoregulation and membrane stabilization and protection and may have contributed to the acclimation process.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Tumoru Sera for the Catucaí IPR 102 and Gabriel Burgarelli for the Conilon plant materials. Thanks also to the CAPES and UENF, for the scholarship. This research was partially supported by FCT and European Fund FEDER (through the projects POCTI/AGG/43101/2001 and PTDC/AGR-AAM/64078/2006).
