ABSTRACT

An experimental inactivated vaccine against bovine herpesvirus-1 (BoHV-1) was produced aiming to evaluate the systemic and local antibody responses in 12 seronegative heifers, after vaccination and revaccination. Serum samples were submitted to virus neutralization assay and to ELISA test for detection of IgG1 and IgG2 isotypes. Nasal secretion samples were submitted to the same ELISA test for detection of IgG1 and IgG2 isotypes. The results showed that moderate to high neutralizing titres and IgG1 and IgG2 antibody responses were induced after the second vaccination in the serum and in nasal secretions up to 114 days post vaccination. IgG2 antibodies were the prevalent isotype for most of the post-vaccination period. The results indicate that BoHV-1 experimental inactivated vaccine elicited potentially protective IgG1 and IgG2 antibody levels, both in the systemic and mucosal compartments.

Key words: BoHV-1, immunoglobulin isotypes, experimental vaccine.

RESUMO

Uma vacina experimental inativada contra o herpesvírus bovino tipo 1 (BoHV-1) foi produzida com o objetivo de se avaliar a resposta imune humoral local e sistêmica contra o BoHV-1, em 12 novilhas soronegativas, após a vacinação e a revacinação. Os soros foram submetidos à prova de vírus-neutralização para quantificação do título de anticorpos neutralizantes e a um ELISA para detecção de IgG1 e IgG2. Os swabs nasais também foram submetidos ao ELISA para detecção de IgG1 e IgG2 na secreção nasal. Os resultados demonstraram que títulos de anticorpos neutralizantes foram induzidos após a revacinação, em níveis moderados a altos,

permanecendo em níveis significativos no soro sanguíneo e na secreção nasal até o dia 114 pós-vacinação. O IgG2 foi o isótipo predominante na maior parte do período pós-vacinação, tanto na secreção nasal, como no compartimento sistêmico. A vacina experimental inativada contra o BoHV-1 estimulou níveis de anticorpos potencialmente protetores dos isótipos IgG1 e IgG2, tanto no compartimento sistêmico, como nas mucosas.

Palavras-chave: BoHV-1, isótipos de imunoglobulinas, vacina experimental.

INTRODUCTION

Bovine herpesvirus-1 (BoHV-1) is an important pathogen in cattle, acting either alone or in association with bacterial pathogens to cause a number of clinical diseases, such as infectious bovine rhinotracheitis (IBR), genital lesions and abortions (FLORES, 2007). In countries with a high prevalence of seropositive animals, the main method of controlling IBR is vaccination of susceptible animals to reduce the virus excretion, and to decrease the severity of clinical signs (MUYLKENS et al., 2007; FLORES, 2007).

A number of protective mechanisms against infection with BoHV-1 have been described which essentially depend upon the induction of a wide spectrum of innate and specific mechanisms of cellular and humoral immune responses. Innate inflammatory

and cellular reactions are the first response to BoHV-1 infection (JONES & CHOWDHURY, 2008). Some of the mechanisms such as complement activation are non-specific, whereas others, such as interferons and early pro-inflammatory cytokines are induced by virus replication and lead to the recruitment and activation of different cells such as macrophages, polymorphonuclear neutrophils and Natural Killer cells in cattle (MUYLKENS et al., 2007; JONES & CHOWDHURY, 2008). The non-specific activated immune cells are also essential in initiating and regulating the specific immune response to BoHV-1 (BABIUK et al., 1996; MUYLKENS et al., 2007).

Since current inactivated BoHV-1 vaccines generally induce strong humoral but weak cell-mediated immune responses, the success of vaccination has been correlated to the ability of neutralizing antibodies to provide protection (MUYLKENS et al., 2007). Indeed, a correlation between neutralizing antibody responses and level of protection has been demonstrated for BoHV-1 (LEMAIRE et al., 1994; VAN DRUNEN LITTEL-VAN DEN HURK et al., 1994; BABIUK et al., 1996). In addition to virus-neutralization, the anti BoHV-1 antibodies can opsonize the virus, activate the complement system, and can mediate the Antibody Dependent Cellular Cytotoxicity (ADCC) (JONES & CHOWDHURY, 2008). Antibody function *in vivo* is chiefly linked to immunoglobulin isotype (McGUIRE et al., 1979), e.g. in bovines, IgG1 antibodies interact with macrophages Fc receptors whereas IgG2 antibodies interact with neutrophils Fc receptors (HOWARD et al., 1980). Anti-BoHV-1 isotype-specific responses were reported and characterized for experimentally infected cattle (GUY & POTGIETER, 1985; MADIC et al., 1995; BRADSHAW & EDWARDS, 1996). However, there are no consistent data in the literature describing the role of antibody isotypes, or even their kinetic production profiles, in bovines immunized with anti-BoHV-1 vaccines formulated with suspensions containing inactivated viral particles. The aim of this research was to develop an experimental vaccine against the herpesvirus type 1 (BoHV-1) using the inactivated virus and to evaluate its immunogenicity in bovines by measuring the levels of neutralizing antibodies, as well as quantifying IgG1 and IgG2 antibodies in the serum and in nasal secretions, over time, following vaccination and revaccination.

MATERIALS AND METHODS

Vaccine preparation

The virus strain used in vaccine production and in the virus neutralization test was the Los Angeles

(ATCC-VR 188; USA). MDBK cell line (ATCC CCL-22) was used for virus propagation. Cells were grown in 150cm² polystyrene T flasks (Corning, USA) using Minimum Essential Medium (MEM) (Cultilab, Brazil) supplemented with 5% foetal bovine serum (Cultilab), with the addition of sodium bicarbonate (Merck, Germany) adjusted to a final pH 7.0. Sub-cultivations were carried out every 72h. To produce the vaccine, an initial cellular inoculum of 0.2×10^6 cells mL⁻¹ was used. After 24 hours of incubation, this pre-formed MDBK cell monolayer was infected with 0.5mL of an $10^{7.5}$ TCID₅₀ mL⁻¹ suspension of BoHV-1 ($10^{7.2}$ TCID₅₀) per 150cm² flasks in 60mL of infection medium, without adsorption step. The infection medium did not contain bovine foetal serum (BFS). Flasks were incubated at 37°C in 5% CO₂ (Thermo Electron Corporation, USA) until 80-90% of the cell monolayer was destroyed by the virus. This viral suspension was collected and centrifuged at 2160xg (PR-2 centrifuge; International Equipment Co., USA) for 15min at 4°C for removal of cellular debris. Infectivity was determined in the supernatant and the viral titre was $10^{7.8}$ TCID₅₀ mL⁻¹. The final viral suspension was stored at 4°C until the inactivation. The clarified and titrated viral suspension was inactivated using 3mM (final concentration) binary ethylenimine (BEI) at 26°C (BAHNEMANN, 1990) for 24 hours. The inactivation was stopped by the addition of a 1M sterile Na-thiosulphate solution at 10% of the volume of the BEI solution used. The suspension was tested for residual infectivity by three consecutive passages of 5 days each in MDBK cultures (1mL of inactivated suspension in 25cm² flasks). The inactivated suspension was then adsorbed onto 20% aluminium hydroxide (produced by Vallée S.A, Brazil) as adjuvant at 4°C, for 12h. Each vaccine dose contained 4mL of the inactivated viral suspension (total titre per dose: $10^{8.4}$ TCID₅₀) and 1mL of adjuvant. No preservatives were added.

Experimental protocol

Seventeen cross-bred heifers, aged between 18 and 24 months, seronegative for BoHV 1 (VN titer ≤ 2), were divided in vaccinated group (12 animals) and unvaccinated control group (5 animals). Vaccinated heifers received 5mL of the experimental vaccine subcutaneously, followed by an identical dose, 25 days later, also subcutaneously. Blood was collected at 0, 9, 18, 25, 32, 46, 60, 86, 114, 150, 210, 270 and 330 days after the first vaccination and the serum was submitted to a temperature of 56°C for 30 minutes to inactivate the complement components; after that, it was frozen until the analysis. Nasal secretions were collected on

cotton swabs (Inlab, Brazil) until 150 days post-vaccination (DPV). After that, the swab was placed in appropriate tubes containing 1mL of MEM with 1% antibiotic for transport to the laboratory. Tubes were agitated 30 seconds and centrifuged at 2160g at 4°C for 10 minutes, and the supernatant was frozen until analysis.

Evaluation of the humoral immune response

Neutralizing antibodies were measured by a standard virus neutralization assay as described by OIE (2008). Serum samples were tested in duplicate. For graphic representation of results, the VN antibody titres were transformed in $\log_2 x + 1$, in which x is the VN antibody titre, because zero is not a valid value to calculate \log_2 .

The general procedure described by the supplier of the ELISA kit for the detection of antibodies against Bovine Infectious Rhinotracheitis Virus (IDEXX, Westbrook, USA) was followed to measure the anti-BoHV-1 antibody isotypes in serum and nasal swab samples, except for the use of anti-bovine IgG1 or anti-bovine IgG2 peroxidase conjugates (Bethyl Laboratories, Montgomery, USA) to replace the anti-bovine total IgG peroxidase conjugate supplied in the kit. The optimal dilutions for anti-IgG1 and anti-IgG2 conjugates were determined by checkerboard titration using as diluent phosphate buffered saline (PBS) with 0.05% Tween 20 (Merck, Germany) and 1.5% ovalbumin (Sigma-Aldrich, USA). Pools of 6 negative,

and 6 strong positive sera in the virus neutralizing test were used to standardize the controls for anti-BoHV-1 IgG1 and anti-IgG2 antibodies. The reading of optical densities (OD) was recorded in an ELISA Multiskan Ascent (Thermo Lasystems, USA) microplate reader at 650nm. The sample to positive values (S/P) was calculated by the following formula:

$S/P = Z \cdot X / Y \cdot X$ (Where Z = OD of the test sample (serum or nasal secretion), X = OD of the negative control, and Y = OD of the positive control).

Statistical analysis

The Kruskal–Wallis non-parametric test was used for the analysis of neutralizing antibody titres and of S/P values of each antibody isotype and, when a significant difference between medians was evident, Dunn's non-parametric test was applied. Differences in P value of ≤ 0.05 were considered significant. Linear regression analysis was performed to determine the relationship between the two variables. Pearson's correlation coefficient was also calculated.

RESULTS AND DISCUSSION

Systemic virus-neutralizing antibody responses

Relevant anti-BoHV-1 VN antibody titres developed in serum of vaccinated animals remained at moderate to high levels from 25 to 210DPV (Figure 1). No relevant VN antibody titres were detected in non-vaccinated animals for the entire post-vaccination

Figure 1 – Kinetics of humoral immune responses in serum of vaccinated and revaccinated animals measured as virus-neutralizing anti BoHV-1 antibody titres (\log_2 reciprocal of the highest dilution) and IgG1 and IgG2 specific anti-viral antibody levels (S/P values in indirect ELISA).

period investigated. After the first vaccination, a maximum of 41.6% (5 out of 12 heifers) of the immunized animals showed a slight elevation of virus-neutralizing antibody production (Figure 1). The revaccination resulted in a significant rise in VN-antibody titres, which was characterized by more than doubling in \log_2 of the antibody titres ($P < 0.01$) (Figure 1). The anti-BoHV-1 median VN-antibody titres reached the acceptable threshold value ($\geq \log_2 = 3$, according to Code of Federal Regulation, US, 2006) and remained at this level in 100% of the animals until 60DPV. The median VN antibodies began to decline towards slightly low titres ($\log_2 = 2.32 \leq \text{VN titres} \leq \log_2 = 2.74$), from 86 to 210DPV, and became negative in the last two sampling times, 270 and 330DPV (Figure 1). The evolution of median VN antibody titres showed also that the highest percentages (50-100%) of vaccinated animals harbouring acceptable levels of these antibodies ($\log_2 \geq 3$) were reached between 32 to 115DPV and declined afterwards to 25-33.3% (150-270DPV). These results, particularly the kinetic profile of the humoral immune response to BoHV-1, resembled to that found, either after the administration of one or two doses of inactivated vaccines (CAMPOS et al., 1990; FULTON et al., 1995). Despite the decline in neutralizing antibody titres, the possibility that animals might yet be protected against the clinical signs induced by an infection of the BoHV-1 cannot be rejected. It has been reported that vaccinated calves, even exhibiting low anti-BoHV-1 antibody titres, showed a peak in the antiviral antibodies in response to challenge performed after six months of vaccination, as a consequence of an anamnestic response that might have contributed to a significant reduction of respiratory clinical signs induced by the virus (PETERS et al., 2004). Additionally, the aluminium hydroxide used as adjuvant in the current investigation may have contributed to the early decline of anti-BoHV-1 neutralizing antibody titres, since its deposit effect is lower than mineral oil (CAMPOS et al., 1990; FULTON et al., 1995). Based on these results, it should be recommended to revaccinate the animals every six months.

Systemic and local IgG1 and IgG2 anti-BoHV-1 antibody responses

As it was tested an inactivated BoHV-1 vaccine containing aluminium hydroxide, which is a good inducer of IgG antibody responses, but is not efficient in raising IgA antibodies (GUPTA, 1998), only IgG1 and IgG2 anti-BoHV-1 isotypes were evaluated in this study.

The first vaccine dose elicited a slight rise in the levels of systemic IgG1 and IgG2 antiviral

antibodies, early as 18DPV, and the revaccination (25 DPV) induced a typical anamnestic response of both isotypes, which was characterized by a sharp increase in the levels of these antibody isotypes after 32 to 60DPV (Figure 1). The levels of IgG1 and IgG2 antibodies started to decline at 86DPV, maintaining moderate levels until 150DPV, and from this point on, these antibodies presented a marked reduction (210-330DPV). The kinetics of the systemic response of anti-BoHV-1 antibodies induced by the experimental vaccine demonstrated that the IgG2 prevailed over IgG1 isotype in vaccinated animals for most of the post-vaccination intervals analysed (Figure 1). The close relationship between anti-BoHV-1 VN antibody titres and IgG1 and IgG2 antibody levels was demonstrated by the similarity of the kinetic curves of these antibodies (Figure 1). Virus-neutralizing antibodies reached maximum concentration at 32DPV, whereas specific anti-virus antibodies of IgG1 and IgG2 isotypes showed the highest concentration at 46DPV (Figure 1). Nevertheless, there were no significant differences between concentrations of neutralizing antibodies at 32 and 46 DPV ($P > 0.05$). Thus, the highest levels of anti-BoHV-1 antibodies of IgG1 and IgG2 isotypes coincided with the peak of neutralizing antibody activity. In addition to this, positive correlation coefficients were also found for VN antibody titres and IgG1 or IgG2 antibody levels, corresponding to $r = 0.865$, and $r = 0.779$, respectively. IgG2 was also the prevailing antibody in nasal secretions of vaccinated animals. This isotype peaked between 32-46DPV, as well as relatively high levels of this immunoglobulin ($S/P \geq 0.5$) were detected in most of the time points investigated (25, 60, 86, and 114DPV), as occurred with the systemic antibodies of this isotype. In contrast, IgG1 antibodies appeared in detectable and significant amounts ($S/P \geq 0.5$) only at 32 and 46DPV (Figure 2). A positive correlation between nasal and circulating IgG1 and IgG2 antibody levels was also found ($r = 0.66$ and 0.866 , for IgG1 and IgG2, respectively, $P < 0.001$), suggesting that there was, at least, a partial transference of these antibodies from systemic to the local compartment, especially for IgG2 antibodies.

The IgG2 isotype showed similar kinetic profiles with regard to those found in serum from of antibody-free calves experimentally infected with BoHV-1 (MADIC et al., 1995). Moreover, the levels of anti-BoHV-1 systemic IgG2 antibodies compared to IgG1 isotype remained higher. These results differ from MADIC et al. (1995) where IgG1 isotype prevailed over IgG2. However, the reason for the prevalence of IgG2 antibodies is unclear, since the regulation of the immune response for the production of a specific

Figure 2 - Kinetics of IgG1 and IgG2 specific anti-BoHV-1 antibody levels (S/P values, in indirect ELISA) in nasal secretion samples of BoHV-1 vaccinated and revaccinated animals.

immunoglobulin isotype is a complex process dependent upon many factors and several parameters may influence the formation of immunoglobulin isotypes, such as the macromolecular form of the immunogen, type of antigen, and the adjuvant used, as demonstrated in the experimental immunization of calves against foot-and-mouth disease virus (MULCAHY et al., 1990).

The protective capacity of each antibody isotype may be interpreted according to its biological activity and, consequently, to its capacity to interact with various immune effector cells or humoral factors, as well as the role of these cells in conferring protection against the pathogen (MULCAHY et al., 1990). Regarding the immune-protection against BoHV-1, antibodies of isotype IgG2 display greater opsonizing activity than those of isotype IgG1 for bovine neutrophils present in peripheral blood (HOWARD et al., 1980; PETERS et al., 2004), thus indicating that there is greater affinity of the receptors of these cells for IgG2 antibodies. On the other hand, antibodies of isotype IgG1 are able to efficiently mediate the phagocytosis process in bovines by mononuclear phagocytes such as macrophages, rather than neutrophils, because these cells express higher numbers of receptors or greater affinity of their receptors for the IgG1 Fc region (HOWARD et al., 1980; MULCAHY et al., 1990). Considering that ADCC constitutes one of the main mechanisms involved in immunity to BoHV-1, and neutrophils are the cells more directly involved in this process (BABIUK et al., 1996), it was suggested that antibodies of IgG2 isotype induced by the inactivated experimental BoHV-1

vaccine in the current study may play an important role in immunity against this virus.

The correlation between concentrations of anti-BoHV-1 IgG1 and IgG2 antibodies in serum and nasal secretion is not an unexpected result, since it has been demonstrated that the intramuscular administration of a subunit vaccine consisting of BoHV-1 glycoproteins is capable of inducing neutralizing antibodies in the nasal mucosa of immunized bovines (BABIUK et al., 1987). Furthermore, the vaccinated animals demonstrated the protection against replication of the viral pathogen associated with neutralizing antibody titres in the nasal secretion, and these local antibodies, in turn, showed a high level of correlation with serum antibody titres (BABIUK et al., 1987). Therefore this finding supports the hypothesis of selective transportation of IgG2 isotype from serum to the nasal mucosa, and indicates that the concentration of such anti-BoHV-1 antibodies in the mucosa, at least in part, depends upon specific anti-BoHV-1 antibodies present in serum (BABIUK et al., 1987).

Systemic and local IgG1 and IgG2 anti-BoHV-1 antibody responses induced by the administration of an experimental inactivated vaccine were well characterized in the current investigation, but the functions of different antibody isotypes in cattle, relative to the specific mechanisms of protection against BoHV-1, need further investigation. Inactivated vaccines, particularly those containing aluminium hydroxide adjuvant, may not be expected to result in a significant cell-mediated immunity or an extensive production of IgA antibodies in the mucosa (McGHEE et al., 1992; GUPTA, 1998). Conversely, the aluminium

hydroxide does stimulate the production of neutralizing IgG antibodies, particularly from IgG2 isotype, as demonstrated here, and they are distributed in blood and in the nasal secretion and may thus block BoHV-1 replication at the initial infection site, as proposed before (ZHU & LETCHWORTH, 1996). However, an important point to be emphasized is the brief half-life of such antibodies in the nasal secretion (Figure 2), making local antibody levels decrease shortly after revaccination.

CONCLUSION

Systemic and local anti-BoHV-1 antibody responses were induced by the experimental inactivated vaccine in the current study. Neutralizing anti-BoHV-1 antibodies were achieved in potentially protective titres until 86 DPV and IgG1 and IgG2 antibody responses were induced after the second vaccination in the serum and in nasal secretions up to 114 days post vaccination. IgG2 antibodies were the prevalent isotype for most of the post-vaccination period. Despite not evaluated in the context of protection against experimental infection, the vaccine-induced antibodies can be used as markers for monitoring the effect of the immunization against this virus in cattle, as well as the presence of anti-BoHV-1 IgG1 and IgG2 antibodies in serum and nasal secretion from bovines immunized with inactivated vaccines. If the isotypes found in the current study may substantiate other effectors mechanisms at the main virus entry site, in addition to the virus neutralization, further investigation are required.
