Relationship between total bacteria counts and somatic cell counts from mammary quarters infected by mastitis pathogens

Relação entre contagem total de bactérias e contagem de células somáticas de quartos mamários infectados por patógenos da mastite

ABSTRACT

This study was conducted to establish the relationship between somatic cell count (SCC) and bacterial shedding from mammary quarters according to mastitis pathogens. Milk samples from 638 mammary quarters were examined for mastitis pathogens, SCC and total bacterial count (TBC). The raw data of SCC and TBC were used to perform descriptive statistics. The significance of the arithmetic mean differences between SCC and TBC according to bacteriological examination results was determined by a two-tailed unpaired t-test. Pearson and Spearman’s correlations were done with logarithmic data and linear regression analyses. The geometric means of the bacteriological examination results were (cells mL⁻¹; CFU mL⁻¹): no growth (52,000; 12,000), coagulase-negative staphylococci (85,000; 17,000), Staphylococcus aureus (587,000; 77,000); other streptococci (432,000; 108,000) and Streptococcus agalactiae (1,572,000; 333,000). The Pearson and Spearman’s correlations between SCC and TBC were higher than 0.60 for all mastitis pathogens. The regression analyses slopes showed different increase in TBC with the same increase in SCC according to mastitis pathogens. The slope for S. agalactiae (0.542) was higher than that for other mastitis pathogens. The results suggest that the intensity of inflammatory process was associated with number of mastitis pathogens shedding from the mammary gland.

Key words: mastitis pathogens, somatic cell count, bacteria shedding

INTRODUCTION

Differences in somatic cell count (SCC) variations and pathological modifications of the

(CCS) and e liberação de bactérias de quartos mamários de acordo com os patógenos da mastite. Amostras de leite de 638 quartos mamários foram examinadas para identificação dos patógenos da mastite, CCS e contagem total de bactérias (CTB). Estatísticas descritivas foram utilizadas para avaliar os dados brutos de CCS e CTB. A diferença entre médias para CCS e CTB foi avaliada pelo teste T para amostras independentes. Foram realizadas a correlação de Pearson, de Spearman e regressão linear com os dados transformados. As médias geométricas de acordo com os resultados dos exames bacteriológicos foram (células mL⁻¹; UFC mL⁻¹): sem crescimento (52,000; 12,000), estafilococos coagulase negativo (85,000; 17,000), Staphylococcus aureus (587,000; 77,000); outros estreptococos (432,000; 108,000) e Streptococcus agalactiae (1,572,000; 333,000). A correlação de Pearson e Spearman entre CCS e CTB foi maior que 0,60 para todos os patógenos da mastite. O coeficiente angular das regressões lineares mostrou diferentes aumentos da CTB como o mesmo aumento da CCS de acordo com os patógenos da mastite. O coeficiente angular para o S. agalactiae (0.542) foi maior em relação aos outros patógenos da mastite. Os resultados sugerem que a intensidade do processo inflamatório foi associada com a quantidade de bactérias da mastite liberada pela glândula mamária.

Palavras-chave: patógenos da mastite, contagem de células somáticas, liberação de bactérias
mammary gland, according to mastitis pathogens, have been reported in previous studies. The major pathogens cause the greatest SCC increases (Staphylococcus aureus, Streptococcus agalactiae, coliforms, and Streptococcus spp. other than S. agalactiae), and the minor pathogens (Corynebacterium bovis and coagulase-negative staphylococci) usually cause only a moderate increase in SCC (SOUZA et al., 2009). Meta-analysis showed the effects associated with intramammary infection (IMI) at the quarter level by a bacterium or a group of bacteria on SCC. This study showed that the geometric mean (GM) of SCC in bacteriologically negative quarters was 68,000 cells mL⁻¹. In cases of IMI, the SCC were 357,000, 138,000, 857,000, 1,024,000 and 547,000 cells mL⁻¹ in quarters infected by Staphylococcus aureus, coagulase-negative staphylococci (CNS), S. agalactiae, Streptococcus uberis and Streptococcus dysgalactiae, respectively (DJABRI et al., 2002).

Cows with udder infection have the potential to shed in excess of 10⁷ bacteria per mL according to (DJABRI et al., 2002). Meta-analysis showed the effects associated with intramammary infection (IMI) at the quarter level by a bacterium or a group of bacteria on SCC. This study showed that the geometric mean (GM) of SCC in bacteriologically negative quarters was 68,000 cells mL⁻¹. In cases of IMI, the SCC were 357,000, 138,000, 857,000, 1,024,000 and 547,000 cells mL⁻¹ in quarters infected by Staphylococcus aureus, coagulase-negative staphylococci (CNS), S. agalactiae, Streptococcus uberis and Streptococcus dysgalactiae, respectively (DJABRI et al., 2002).

Previous studies (SEARS et al., 1990; ZADOKS et al., 2004) showed that mastitis seldom contributed large numbers of bacteria to the raw milk bulk tank. Nevertheless, the relationship between mastitis pathogens number in bulk tank milk and the percentage of infected cows showed significant a positive correlation (ZADOKS et al., 2004; RYSANEK et al., 2005). However, there is a scarcity of studies designed to assess the bacteria-shedding pattern from infected mammary gland by different mastitis pathogens. The purpose of the present study was to evaluate the shedding of bacteria from mammary quarters according to mastitis pathogens and its relationship with SCC.

MATERIAL AND METHODS

Sampling procedure

From June 2009 through December 2009, milk samples from 638 mammary quarters without clinical mastitis were collected. These mammary quarters were from 124 cows on five dairy farms located in Minas Gerais State, Brazil. From each mammary quarter, we collected three milk samples into three different vials. Teats were washed with water and then pre-dipped with a chlorine solution (150 ppm) and dried with individual paper towels after 20-30 seconds. Beginning with the teat farthest from the milker, all four teats were scrubbed with gauze moistened with 70% alcohol. Beginning with the teat closest to the milker, one or two streams of foremilk were discarded from each teat, and, for first quarter sampling, 5 to 10 mL of milk from each quarter was collected in a separate sterile vial for bacteriological examination. The second and third milk samples of each quarter, 30 to 40 mL, were used to determine total bacterial count (TBC) and SCC, respectively. The aseptic sampling procedures for bacteriological examination are described by HARMON et al. (1990). The sampling procedures for TBC and SCC were performed according to international standard (ISO 707, 2008).

Bacteriological examination

Bacteriological culturing of milk samples was performed according to the standards of the National Mastitis Council (HARMON et al., 1990).

Somatic cell count and total bacterial count

SCC were performed using a Bentley Somacount 300 (CHASKA, MN) and TBC determination was performed by direct counting of the bacterial cells using a Bentley IBC (CHASKA, MN).

Statistical analyses

Descriptive statistics and percentiles were performed, using the SCC and TBC values (Table 1) according to the bacteriological examination results. The normality of the raw data (SCC and TBC) distribution was tested. To be able to work with the normal distribution data, we carried out a logarithmic transformation (with logarithm base 10). The significance of the arithmetic mean differences between the log₁₀SCC (Table 2) and log₁₀TBC (Table 2) values according to the bacteriological examination results was determined by a two-tailed unpaired t-test. Linear regression analyses were done using the log₁₀TBC of each mastitis pathogen isolated plus the log₁₀TBC of the milk samples with no growth in the bacteriological examination as the dependent variable (y) and using the log₁₀SCC of the same mammary quarters as the independent variable (x). Thus, four linear regression analyses were performed to compare the slope among mastitis pathogens. A comparison was made between the Pearson correlation coefficients and the Spearman rank correlation coefficients. The linear regression and correlation coefficients were evaluated for statistical significance (Table 3).
Relationship between total bacteria counts and somatic cell counts from mammary quarters infected by mastitis pathogens.

RESULTS

In table 1, the descriptive statistics of SCC and TBC according to bacteriological examination results are shown. Of the 638 total mammary quarter milk samples, 421 (66.0%) demonstrated no growth in the bacteriological examination. The SCC geometric mean and median were 52,000 and 70,000 cells mL⁻¹, respectively. Mastitis pathogens isolated from mammary quarter milk samples were *S. aureus* (69/10.8%), coagulase negative staphylococci CNS (64/10.0%), *S. agalactiae* (45/7.1%) and other streptococci (39/6.1%). The higher geometric mean and median SCC observed for *S. agalactiae* were 1,572,000 and 1,839,000 cells mL⁻¹, respectively. *S. aureus* (587,000 and 742,000 cells mL⁻¹) and other streptococci (432,000 and 414,000 cells mL⁻¹) demonstrated higher values. The lower values for the descriptive statistics of the SCC according to mastitis pathogens were for CNS, with values close to being bacteriologically negative. The arithmetic mean of the log_{10}SCC (Table 3) according to the bacteriological examination results increased in this order: no growth, CNS, other streptococci, *S. aureus* and *S. agalactiae*. Analysis of the arithmetic mean differences between the log_{10}SCC revealed a significant difference between bacteriological examination results (P<0.05). Bacteriologically negative quarters had the lower log_{10}SCC arithmetic means (1.71) and were different from CNS (1.93). The *S. aureus* (2.77) and other streptococci (2.64) log_{10}SCC arithmetic means were different from CNS and *S. agalactiae* (3.20) but both had equal log_{10}SCC arithmetic means (P>0.05).

The TBC geometric mean and median in bacteriologically negative quarters were 12,000 and 10,000 cfu mL⁻¹, respectively. The values of descriptive statistics for TBC according to mastitis pathogens did not have the same order as SCC. The higher values of the geometric mean and median were for *S. agalactiae*.

BER - bacteriological examination results; NG - no growth; CNS - coagulase negative staphylococci; STA - *Staphylococcus aureus*; STR - other streptococci; SAG - *Streptococcus agalactiae*; SD - standard deviation; CI - confidence interval (95%). Different letters between rows indicate statistic significance by two-tailed unpaired t-test (P<0.05).
(333,000 and 590,000cfu mL⁻¹). Other streptococci (108,000 and 100,000cfu mL⁻¹) and S. aureus (77,000 and 66,000cfu mL⁻¹) presented with higher TBC values. The TBC geometric mean (17,000cfu mL⁻¹) and median (15,000cfu mL⁻¹) for CNS were as for SCC, in other words, close to bacteriologically negative quarter values. Analysis of the arithmetic mean differences between the log₁₀ TCB revealed a significance between bacteriological examination results (P<0.05). The arithmetic mean of the log₁₀ TBC (Table 3) according to bacteriological examination results increased in a different order than the log₁₀ SCC. The order was as follows: no growth, CNS, S. aureus, other streptococci and S. agalactiae. In this situation, no difference (P=0.05) was observed between the log₁₀ TBC arithmetic mean for no growth (1.09) and CNS (1.22). S. aureus and other streptococci had no difference in the log₁₀ TBC arithmetic mean (P>0.05). However, these were different (P<0.05) from the no growth, CNS and S. agalactiae arithmetic means. The geometric mean and median, which are relatively non-affected by extreme high values, better indicated the central number of the SCC and TBC found in mammary quarter milk samples than did the arithmetic mean. Large standard deviations were found for each mastitis pathogen in SCC and TBC, indicating that the data set had a great deal of variation. Because of the wide range of SCC and TBC results, logarithmic transformation was performed for comparison between means and the association between SCC and TBC. The corresponding Spearman’s rank correlations and Pearson correlations were in agreement (Table 2). Spearman and Pearson correlations used the logarithmic transformation of SCC and TBC. The correlation coefficients found between log₁₀ SCC and log₁₀ TBC for S. agalactiae (0.674, Spearman; 0.657, Pearson), S. aureus (0.677, Spearman; 0.659, Pearson), other streptococci (0.665, Spearman; 0.654, Pearson) and CNS (0.632, Spearman; 0.626, Pearson) were moderately high (P<0.01). The linear regression model significances were high (P<0.001) and showed different slopes for each mastitis pathogen (Table 3). In order, the higher slope was found for S. agalactiae (0.542), S. aureus (0.503), other streptococci (0.486) and CNS (0.440).

DISCUSSION

In mammary quarter milk samples that were not observed to have growth in the bacteriological examination, the geometric mean of the SCC was 52,000 cells mL⁻¹. The 95% confidence interval of individual values based on standard deviation varied between 205,000 and 357,000 cells mL⁻¹. A meta-analysis study on quarter milk SCC in dairy cows found 68,000 cells mL⁻¹ to be the geometric mean in the absence of a diagnosed infection (DJABRI et al., 2002). The summary SCC values in bacteriologically negative quarters were between 68,000 and 187,000 cells mL⁻¹. The SCC geometric means of mammary quarters classified as not infected in this study and by DJABRI et al., (2002) were close and it could be considered equal in theoretical and practical approach. The SCC geometric mean found in the present study for S. agalactiae (1,572,000 cells mL⁻¹) was also close to the value found in the meta-analysis study (1,129,000 cells mL⁻¹). Among the causative pathogens of subclinical cases, such as S. aureus, S. agalactiae, CNS and other streptococci (HARMON, 1994), SCC values for S. agalactiae were higher than other mastitis pathogens in both studies. The highest SCC identified among mastitis pathogens found by DJABRI et al. (2002) was caused by Escherichia coli, but this pathogen usually promotes clinical mastitis due to virulence factors and consequently pathophysiological processes (HARMON, 1994; HOGAN & SMITH, 2003). The SCC geometric mean for S. aureus (587,000 cells mL⁻¹) was twice as high as that found in the meta-analysis study (333,000 cells mL⁻¹). The inverse situation was observed for CNS, in the meta-analysis study, the SCC geometric mean was 155,000 cells mL⁻¹, and in present study it

BER - bacteriological examination results; NG - no growth; CNS - coagulase negative staphylococci; STA - Staphylococcus aureus; STR - other streptococci; SAG - Streptococcus agalactiae; ¹ Spearman’s rank correlation; ** (P<0.01); *** (P<0.001).
Relationship between total bacteria counts and somatic cell counts from mammary quarters infected by mastitis pathogens.

The studies cited in the meta-analysis evaluated SCC from mammary quarters infected by *Streptococcus uberis* and *Streptococcus dysgalactiae*. Although the present study did not identify *S. uberis* and *S. dysgalactiae*, the SCC geometric mean value for other streptococci was 432,000 cells mL⁻¹. Data reported by DJABRI et al. (2002) showed that SCC geometric means for *S. uberis* and *S. dysgalactiae* were 1,024,000 and 547,000 cells mL⁻¹, respectively. The SCC geometric mean for other streptococci was higher, but the values contained in the confidence interval overlapped in both studies. Thus, it cannot be suggested, based on these results that most of the other streptococci were *S. dysgalactiae* than *S. uberis*, but the values contained in the confidence interval overlapped in both studies. This correlation was few compared to *S. aureus*, other streptococci, CNS and coliform bacteria. However, *S. uberis* was identified as a mastitis pathogen causing TBC peaks in bulk tank milk, ranging from 14,000 to 60,000 cfu mL⁻¹ (HAYES et al., 2001; ZADOKS et al., 2004). Thus, the impact of mastitis pathogens on bulk tank TBC depends on the percentage of infected mammary quarters and type of bacterial mastitis pathogen involved. The stage of infection can also contribute, with an increased shedding of bacteria from the mammary gland according to the stage of infection. These results showed that *S. agalactiae* and other streptococci can cause TBC peaks in bulk tank milk (HAYES et al., 2001; ZADOKS et al., 2004). As mentioned previously, the magnitude of the peak of bulk tank milk TBC will depend on the percentage of infected mammary quarters, the strain of bacteria and stage of infection.

**CONCLUSION**

In conclusion, the greater the intensity of the inflammatory process, the greater was the shedding of bacterial mastitis pathogens from the mammary gland. However, the magnitude of shedding of mastitis pathogens from the mammary gland was different according to mastitis pathogens. The combination of SCC and TBC from mammary quarters may be useful as screening test for streptococci mastitis. More studies are necessary to better understand the variation in the shedding of mastitis pathogens according to the age, parity, lactation stage and infection stage of the cow.
