The van Hemmen model with a random field is studied to analyze the tricritical behavior in the Ising spin glass phase. The free energy and phase diagram (T versus H and T versus J_o/J , where H is the root mean square deviation of the magnetic field, J_o and J are the ferromagnetic and root mean square deviation exchange, respectively) are calculated for the model with discrete (or bimodal) and Gaussian distributions. For the case of the bimodal probability distribution (random field and exchange), we have the presence of three ordered phases, namely: spin glass (SG), mixed (IJ) and ferromagnetic (F). The root mean square deviation of the random field H destroys the spin glass and mixed phases. The mixed phase doesn't appear with Gaussian distribution. In the plane T versus H , we analyze the tricritical behavior for the case of the bimodal distribution, and we compare it with the results obtained by using the Gaussian distribution that presents only second-order phase transition.

Keywords: Spin glasses; Random fields; van Hemmen model; Tricritical behavior

I. INTRODUCTION

The study of the random field Ising model (RFIM) has been a topic of great interest in recent years because of its physical realization as a diluted Ising antiferromagnet in the presence of a uniform magnetic field along the uniaxial direction [1]. The lower critical dimension of the RFIM, above which there exists a stable ferromagnetic state at low temperatures, has been suggested by Imry and Ma [2] that is $d_l = 2$. Using mean field approximation, the nature of the phase transition depends on the distribution associated with the magnetic field. For the Gaussian distribution, the phase transition is always continuous [3], and with symmetric bimodal distribution the phase transition is continuous in the region of low and high temperature, becoming first order for sufficiently large values of magnetic field (random) and low temperature [4]. Study of the three-dimensional RFIM using Monte Carlo simulation detects a jump in the magnetization but no latent heat for both bimodal [5] and Gaussian [6] distributions. However, in four dimensions a zero temperature scaling analysis [7] leads to a first-order phase transition in the bimodal case and a continuous one for a Gaussian distribution, which is in agreement with the mean-field predictions. The use of the mean-field approximation at zero temperature has shown that the order parameter exponent (β) varies continuously with the disorder, under the power law distribution of random field [8], i.e., *non-universal* behavior.

The diluted antiferromagnet $\text{Fe}_x\text{Zn}_{1-x}\text{F}_2$, due to large crystal-field anisotropy, when submitted to an external uniform magnetic field become good experimental realization of the RFIM [9] for large enough values of the concentration x . As x decreases, they behave like Ising spin glass. The spin glass theory has been a difficult problem in statistical mechanics [10]. For many years there has been great controversy on whether the spin glass transition is either of ther-

modynamical or of dynamic nature. A number of physical examples exist. The canonical cases are the metallic alloys with substitutional magnetic impurities, such as CuMn and AuFe. A necessary requirement sums to be a locally random competition between ferromagnetic and antiferromagnetic interactions. However this competition may have a number of possible microscopic states, for example, fixed positions but random exchange, fixed exchange interaction as a function of distance but random positions (RKKY interaction), etc.

Recently, the Ising spin glass with random field in the version of the model proposed by Sherrington and Kirkpatrick (SK) [11] has been treated for Gaussian [12] and bimodal [13] distributions (characterized by a mean value $\langle H_i \rangle = 0$ and the root mean square deviation $H = \sqrt{\langle H_i^2 \rangle}$). The joint study of spin glass and random field problems has been proposed as an appropriate system for the description of mixed hydrogen-bonded ferroelectrics and antiferroelectrics, the so-called proton and deuteron glasses [14, 15], which may be considered as the electric counterparts of magnetic spin glass. On the experimental front, certain classes of randomly dilute antiferromagnets [9], the phase separation of binary fluids in porous media [16]-[18] and the liquid-vapor critical point in porous media [19] are also all believed to be realizations of the RFIM.

Experimental works in the $\text{Fe}_x\text{Zn}_{1-x}\text{F}_2$ compound suggest that for $x \geq 0.40$ one gets a RFIM, whereas for $x \leq x_p = 0.24$ (percolation concentration) it becomes an Ising spin glass (ISG). On the other hand, for intermediate concentrations ($0.25 \leq x \leq 0.40$) a crossover between the RFIM and ISG for small and large magnetic fields, respectively is clearly observed in measurements of $\text{Fe}_{0.31}\text{Zn}_{0.69}\text{F}_2$ [20]-[22].

In the present paper, we study the influence of the random field on the spin glass mean field model introduced by van Hemmen [23]. This model is exactly soluble and unlike the Sherrington-Kirkpatrick [11] model (SK), its solution

does not require the use of the replica trick. In spite of being non-realistic, mean field models give a first qualitative understanding of the thermodynamic behavior. Among these are the susceptibility cusp at the freezing temperature T_f and the field-induced transition away from the spin glass phase at finite magnetic field. Recently, the quantum version (presence of a transverse magnetic field) [24] and an additional multi-spin interactions [25] in the van Hemmen model have been treated in the literature.

The outline of the remainder of the paper is as follows: In Section 2, we introduce the model, where obtain an analytical expression for the free-energy and equations of state. In Section 3, we exhibit and discuss the phase diagrams. Finally, in Section 4 we present our conclusions.

II. MODEL AND FORMALISM

To treat the influence of the random field in the spin glass phase, we generalize the van Hemmen model of spin glass, that consists of a fully connected lattice of N Ising spins with a random field described by the following Hamiltonian:

$$\mathcal{H} = -\frac{J_o}{N} \sum_{(i,j)} S_i \cdot S_j - \sum_{(i,j)} J_{ij} S_i \cdot S_j - \sum_i H_i S_i, \quad (1)$$

where (i, j) denotes a sum over all possible pairs of spins, J_o represents a ferromagnetic interaction, H_i is the random field, $S_i = \pm 1$ is the spin variable at site i , J_{ij} is the spin glass random coupling given by

$$J_{ij} = \frac{J}{N} (\xi_i \eta_j + \xi_j \eta_i), \quad (2)$$

where the ξ_i 's, η_i 's and H_i are independent, identically distributed random variables with even distribution around zero and a finite variance.

In the model (1), the ferromagnetic bonds (J_o) favour a parallel alignment of the spins whereas antiferromagnetic bonds (random exchange J_{ij}) favour an antiparallel alignment. The competition of ferromagnetic and antiferromagnetic bonds induce *frustration*, ingredient to a spin glass model. In particu-

lar, we restrict ourselves to the cases the two different distributions: discrete (or bimodal distribution) given by

$$\mathcal{P}(x_i) = \frac{1}{2} [\delta(x_i - \sigma_{x_i}) + \delta(x_i + \sigma_{x_i})], \quad (3)$$

and the Gaussian (continuous distribution)

$$\mathcal{P}(x_i) = \frac{1}{\sqrt{2\pi\sigma_{x_i}^2}} \exp[-x_i^2/(2\sigma_{x_i}^2)], \quad (4)$$

where $x_i \equiv \xi_i$, η_i , H_i , $\sigma_\xi = \sigma_\eta = 1$ and $\sigma_H = \sqrt{\langle H_i^2 \rangle} \equiv H$. The parameters H and J are the square-root deviation of the probability distribution associated with the random magnetic field and exchange couplings, respectively.

In the thermodynamic limit $N \rightarrow \infty$, the van Hemmen model has three order parameters [23]

$$m = \lim_{N \rightarrow \infty} \left\{ \frac{1}{N} \sum_{i=1}^N \langle S_i \rangle \right\}, \quad (5)$$

$$q_1 = \lim_{N \rightarrow \infty} \left\{ \frac{1}{N} \sum_{i=1}^N \langle \xi_i S_i \rangle \right\}, \quad (6)$$

and

$$q_2 = \lim_{N \rightarrow \infty} \left\{ \frac{1}{N} \sum_{i=1}^N \langle \eta_i S_i \rangle \right\}, \quad (7)$$

which have to be chosen in such a way that $\vec{M} = (m, q_1, q_2)$ minimizes a certain free-energy functional. The number of independent random variables is $2N$ in contrast with $\frac{N^2}{2}$ of SK model. Thus we have a random-site problem and not a random-bond problem as in most other SG models, in agreement with the experimental situation.

The second term of the Hamiltonian (1) can be separable, i.e.,

$$\sum_{i \neq j} (\xi_i \eta_j + \xi_j \eta_i) S_i S_j = \left[\sum_{i=1}^N ((\eta_i + \xi_i) S_i) \right]^2 - \left(\sum_{i=1}^N \eta_i S_i \right)^2 - \left(\sum_{i=1}^N \xi_i S_i \right)^2 - 2 \sum_i \xi_i \eta_i, \quad (8)$$

so that the Eq. (1) can be rewritten as

$$\begin{aligned} \mathcal{H} = & -\frac{J_o}{N} \sum_{(i,j)} S_i \cdot S_j - \frac{J}{N} \left\{ \left[\sum_{i=1}^N ((\eta_i + \xi_i) S_i) \right]^2 - \left(\sum_{i=1}^N \eta_i S_i \right)^2 - \left(\sum_{i=1}^N \xi_i S_i \right)^2 \right\} \\ & + 2 \frac{J}{N} \sum_i \xi_i \eta_i - \sum_i H_i S_i, \end{aligned} \quad (1)$$

In order to study theoretically the thermal properties of the

relevant system described by the above Hamiltonian (1), we

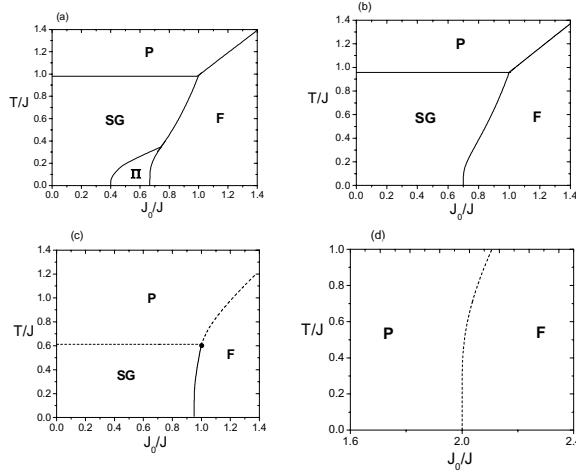

FIG. 1: Phase diagram in the plane T/J versus J_o/J for the van Hemmen spin glass model with a symmetric **bimodal** random field and various magnitude of $\delta = H/J$. The full and dashed lines represent second-order (continuous) and first-order phase transitions, respectively. The ferromagnetic (F), spin glass (SG) and mixed (Π) critical frontiers change qualitatively for increasing values of δ . (a) $\delta = 0.10$; (b) $\delta = 0.20$; (c) $\delta = 0.45$; (d) $\delta = 1.0$.

have to calculate the partition function

$$Z = \text{Tr}\{\exp(-\beta\mathcal{H})\} = \sum_{\mu} \langle \mu | \exp(-\beta\mathcal{H}) | \mu \rangle, \quad (10)$$

for the orthogonal complete set of states $|\mu\rangle$, where we use the Gaussian identity

$$\exp(\alpha x^2) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dy \exp\left(-\frac{y^2}{2} + \sqrt{2\alpha}xy\right) \quad (11)$$

Performing the trace and using steepest descent integrations, we obtain, after some algebra, the following expression for the free-energy per spin

$$\beta f(m, q) = \frac{\beta}{2} (J_o m^2 + 2Jq^2) - \langle \ln[2 \cosh(\beta W)] \rangle_c, \quad (12)$$

whose minimum corresponds always to $q_1 = q_2 = q$ and the equations of states are given by

$$m = \iiint \mathcal{P}(\xi) \mathcal{P}(\eta) \mathcal{P}(H_i) d\xi d\eta dH_i \tanh(\beta W) \quad (13)$$

and

$$q = \iiint \mathcal{P}(\xi) \mathcal{P}(\eta) \mathcal{P}(H_i) d\xi d\eta dH_i \frac{(\eta + \xi)}{2} \tanh(\beta W), \quad (14)$$

where $W = H_i + J_o m + Jq(\xi + \eta)$ and the notation $\langle \dots \rangle_c$ denote the average over the random variable η, ξ and H_i .

III. RESULTS AND DISCUSSION

In the limit of null random field, the above equations reduce to the same expressions obtained by van Hemmen [23]. The

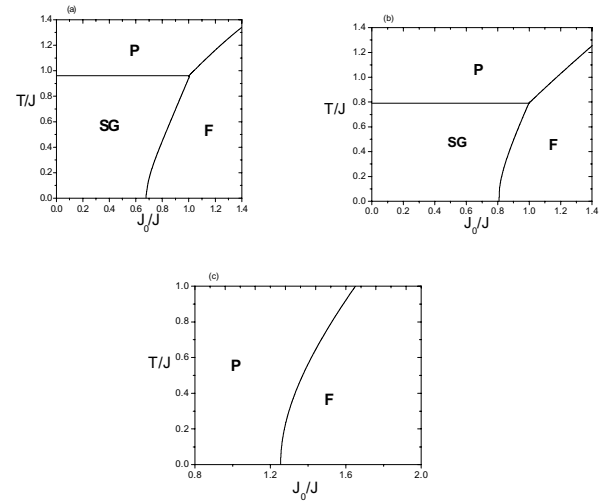

FIG. 2: Phase diagram in the plane T/J versus J_o/J for the van Hemmen spin glass model with a **Gaussian** random field and various magnitude of $\delta = H/J$. The ferromagnetic (F) and spin glass (SG) critical frontiers change qualitatively for increasing values of δ : (a) $\delta = 0.20$; (b) $\delta = 0.45$; (c) $\delta = 1.0$.

phase diagram in the $(T/J, \alpha)$ plane, where $\alpha = J_o/J$ and the Boltzmann constant $k_B = 1$, presents three ordered phases: i) **Ferromagnetic-F**; ii) **Spin Glass-SG** and **Mixed- Π** phases. The mixed phase doesn't appear for the case of the Gaussian distribution. The F, SG and Π phases are determined by means of two order parameter, m and q which are the magnetization and the spin-glass order parameter, respectively. When m and q are nonzero, we have the Π phase. The F and SG phases are characterized by $(m \neq 0, q = 0)$ and $(m = 0, q \neq 0)$, respectively. A stable phase (m, q) corresponds to a global maximum of the free energy functional, Eq. (12), whereas a metastable phase gives rise to a global maximum.

In Fig. 1, we present the phase diagram in the $(T/J, \alpha)$ plane for some values of $\delta = H/J$ with **bimodal distribution**. We also have the paramagnetic phase (P) corresponding to the trivial solution $m = q = 0$. The critical frontiers (F-SG, F- Π , SG-P, SG- Π and F-P) are obtained numerically from Eq.(12) equating the free energies by imposing the conditions for the m and q parameters in the respective phases (F, Π , SG, P), and also using Eqs. (13) and (14). It can be seen that the effect of the random field is to destroy the SG and Π ordered phases (Fig. 1a). For $\delta > \delta_{1c} = 0.17$ the mixed phase (Π) disappears (see Fig. 1b). An interesting behavior is observed for small range of field magnitudes, that for $0.44 < \delta < 0.50$ one observes a first-order phase transition in the SG-P and F-P critical frontiers, while in the case of the F-SG critical frontier, we don't have latent heat, i.e., the phase transition is of second-order (Fig. 1c). For $\delta > \delta_{2c} = 0.5$, the SG phase is destroyed and only the F phase is present in the phase diagram with a phase transition of first-order (Fig. 1d).

On the other hand, for the case of the Gaussian distribution we do not observe first-order phase transition. In Fig. 2 the phase diagram in the $(T/J, \alpha)$ plane for some values of $\delta =$

FIG. 3: Phase diagram in the plane T/J versus H/J for the van Hemmen spin glass model with bimodal and Gaussian random field for $\alpha = 0$.

H/J with Gaussian distribution is presented. We have found analytically a critical field $\delta_c = \sqrt{\frac{2}{\pi}} \simeq 0.80$, where for $\delta > \delta_c$ the SG phase is destroyed and the F phase exists for all value of finite random field, F-P critical line being the a phase transition of second-order.

In Fig. 3, we present in the plane T/J versus δ the behavior of the critical temperature for the SG-P phase transition for the cases of bimodal and Gaussian distributions. The most interesting effect exhibited in Fig. 3 is the presence of a tricritical point (TCP) in the VH model when the random field described by bimodal distribution. In the null temperature limit we obtain $\delta_{2c} = 0.50$ that separates the SG and P phases by a phase transition of first-order. On the other hand, for the case of Gaussian distribution we found the value of the criti-

cal field $\delta_c = \sqrt{\frac{2}{\pi}} \simeq 0.80$ where the temperature goes to zero with a second-order phase transition.

IV. CONCLUSIONS

In conclusion, we have studied the van Hemmen spin glass model in the presence of a random field. We have analyzed the phase diagram for the cases of bimodal and Gaussian distributions in the random field. For the case of the bimodal distribution we observe three ordered phases, namely: F (ferromagnetic), SG (spin glass) and Π (mixed). The mixed phase does not appear with Gaussian distribution. We have shown that for $\delta > \delta_{1c} = 0.17$ the mixed phase disappear, while the SG phase gets destroyed (disappear) at $\delta > 0.50$ for the bimodal distribution and at $\delta > \sqrt{\frac{2}{\pi}} \simeq 0.80$ for the Gaussian distribution. Only the F-P phase transition is present all through. We have observed first-order phase transition between the SG-P and F-P phase transitions for the case of the bimodal distribution in small range of field magnitude $0.44 < \delta < 0.50$. For the same probability distribution at $\delta > 0.50$ the SG phase is destroyed and the F-P phase transition is of first-order. On the other hand, in the case of Gaussian distribution the phase transitions are all of second-order.
