Abstract. A new poly(amide-imide)-montmorillonite series were generated through solution intercalation technique. Cloisite® 20A was used as a modified montmorillonite for ample compatibility with the poly(amide-imide) (PAI) matrix. The PAI 5 chains were synthesized by the direct polycondensation reaction of N-trimellitylimido-L-alanine (3) with 4,4’-diamino diphenyl ether (4) in the presence of triphenyl phosphate (TPP), CaCl2, pyridine and N-methyl-2-pyrrolidone (NMP). Structure and morphology of the resulting PAI-nanocomposite films 5a-5d with (5-20 Wt%) silicate particles were characterized by FTIR spectroscopy, X-ray diffraction (XRD), and scanning electron microscopy (SEM). The effect of clay dispersion and the interaction between clay and polymeric chains on the properties of nanocomposites films were investigated by using UV-Vis spectroscopy, thermogravimetric analysis (TGA), and water uptake measurements.

Keywords: Poly(amide-imide), nanocomposite, solution intercalation technique, Polycondensation.

Introduction

Polymer-clay nanocomposites typically exhibited mechanical, thermal and gas barrier properties, which are superior to those of the corresponding pure polymers [1-9]. Unique properties of the nanocomposites are usually observed when the ultra fine silicate layers are homogenously dispersed throughout the polymer matrix at nanoscale. The uniform dispersion of silicate layers is usually desirable for maximum reinforcement of the materials. Due to the incompatibility of hydrophilic layered silicates and hydrophobic polymer matrix, the individual nanolayers are not easily separated and dispersed in many polymers. For this purpose, silicate layers are usually modified with an intercalating agent to obtain organically modified clay prior to use in nanocomposite formation [10-11]. Also aromatic polyimides are well recognized as a class of high performance materials due to their remarkable thermal and oxidative stabilities and excellent electrical and mechanical properties for long time periods of operation [10-12]. Unfortunately, strong interaction between polyimide chains and their rigid structure make them intractable. Poor thermoplastic fluidity and solubility are the major problems for wide application of polyimides. Thus, to overcome these processing problems various approaches have been carried out by incorporating flexible units such as –NH–CO–, –O–, and –SO2–, and some of which are commercialized [12-14]. Among them, polyamide-imide (PAI) is the most successful material, which combines the advantages of high-temperature stability and processability [15-23]. In this article two PAI-nanocomposite films with 5, 10, 15 and 20% silicate particles containing chiral N-trimellitylimido-L-Alanine moiety in the main chain was prepared by using a convenient solution intercalation technique.

In this report, nanocomposites of poly(amide-imide) with organoclay have been synthesized using a solution technique. Poly(amide-imide) was prepared by reacting 4,4-diamino diphenyl ether (4) with N-trimellitylimido-L-alanine (3) in N-methyl-2-pyrrolidone (NMP). Structure and morphology of the PAICN were determined by FT-IR, UV-Vis, XRD and SEM, TGA and water absorption measurements.

Results and Discussion

Monomer Synthesis

N-Trimesitylimido-L-alanine (3) was synthesized by the condensation reaction of one equivmolar of trimellitic anhydride (1) with one equivmolar of L-alanine (2) in an acetic acid solution (Scheme 1). The chemical structure of diacid 3 was confirmed by FT-IR and 1H-NMR spectroscopy.

Polymer synthesis

Poly(amide-imide) 5 was synthesized by the direct solution polycondensation reaction of an equimolar mixture of diacid 3,
Preparation of New Series of Poly(amide-imide) Reinforced Layer Silicate Nanocomposite Containing N-Trimellitimide-L-Alanine

an equimolar mixture of diamine 4 by using triphenyl phosphite (TPP) and pyridine as condensing agents (Scheme 2). PAI 5 was obtained with good yield (97%) and good inherent viscosity at 25 °C in N-methyl-2-pyrrolidone (NMP) (0.64 dL·g⁻¹). The structure of resulting polymer 5 was confirmed as PAI by using FTIR spectroscopy and elemental analyses. The resulting polymer have absorption band between 1780 and 1710 cm⁻¹ due to imide and amide carbonyl groups. Absorption bands around 1380 cm⁻¹ and 727 cm⁻¹ demonstrated the presence of the imide heterocyclic absorption in these polymers. Also absorption band of amide group appeared at 3414 cm⁻¹ (N-H stretching). The elemental analysis value of the resulting polymer was in good agreement with the calculated values for the proposed structure.

PAI-nanocomposite films

PAI-Nanocomposites were prepared by solution mixing of the appropriate amounts of Cloisite® 20A and PAI into 50 mL flask for a particular concentration. The mixture was agitated at a high speed for 24 h for uniform dispersion of organoclay in the PAI matrix. Different compositions of the hybrid materials having 5, 10, 15, and 20 wt.% organoclay were prepared as mentioned above to give nanocomposite films 5a-5d, respectively. Thin nanocomposite films were cast by pouring the hybrid solution into Petri dishes placed on a leveled surface. The solvent was evaporated at 70 °C for 8 h and hybrid films were further dried at 80 °C under vacuum to a constant weight.

PAI-nanocomposite films were transparent and yellowish brown in color. The incorporation of organoclay changed the color of films to dark yellowish brown. Moreover, a decrease in the transparency was observed at higher clay contents. Scheme 3 show the flowsheet diagram and synthetic scheme for PAI-nanocomposite films 5a-5d.

FT-IR spectroscopy analyses

FT-IR spectroscopy spectra of PAI-nanocomposite films 5b and 5d showed the characteristic absorption bands of the Al-O and Mg-O moieties at 1038, 510 and 458 cm⁻¹ respectively. The incorporation of organic groups in PAI-nanocomposite films was confirmed by the presence of peaks around 1772, 1720, 1383, 727 (imide rings) and 1660 (amide carbonyl group) cm⁻¹.

Figure 1. The FTIR spectra of PAI (5), 5b, 5d.
X-ray diffraction analysis

The XRD is most useful for the measurement of interlayer spacing of the organoclay upon the formation of the nanocomposites. It supplies information on the change of d-spacing of ordered immiscible and ordered intercalated nanocomposites. Fig. 3 shows the XRD patterns of PAI-nanocomposite films 5a-5d containing 5-20 wt.% of silicate particles (Table 1). The Cloistite® Na gives a distinct peak around 2θ equal to 8.93, which corresponds to a basal spacing of around 1.00 nm. The organically modified (Cloistite® 20A) employed for the preparation of nanocomposites has a typical peak at 2θ equal to 6.65 (1.491 nm) increased d-spacing. When the amount of organoclay increased (5-20 wt.%) in the nanocomposites, small peaks appeared at 2θ = 6.05, 5.65, 4.80 and 4.36 corresponding to d-spacing 1.653, 1.623, 1.594 and 1.588 nm, respectively. These results indicated significant expansion of the silicate layer after insertion PAI chains. The shift in the diffraction peaks PAI-nanocomposite films confirms that intercalation has been taken place. This is direct evidence that PAI-nanocomposites have been formed as the nature of intercalating agent also affects the

Figure 2. X-ray diffraction patterns of Cloistite® Na® (5f), Organoclay (5m), PAI-nanocomposite films 5a, 5b, 5c, and 5d.

Figure 3. SEM micrographs of the PAI 5 (a) and nanocomposites with various silica contants (Wt%): (b) 5; (c) 10; (d) 15.
organoclay dispersion in the polymer matrix. Usually there are two types of nanocomposites depending upon the dispersion of clay particles. The first type is an intercalated polymer clay nanocomposite, which consists of well ordered multi layers of polymer chain and silicate layers a few nanometers thick. The second type is an exfoliated polymer-clay nanocomposite, in which is there is a loss of ordered structures due to the extensive penetration of polymer chain into the layer silicate. Such part would not produce distinct peaks in the XRD pattern [24]. In our PAI-nanocomposite films there are coherent XRD signal at 6.05 °, 5.65, 4.80, and 4.36 ° related to 5, 10, 15, and 20 wt.% nanocomposite films, 5a-5d, respectively.

**Scanning electron microscopy**

In order to investigate the morphology, fractured surfaces of PAI-nanocomposite films were studied using SEM. The micrographs of the PAI 5 (a) and nanocomposites containing 5, 10 and 15 wt% silica in the matrix are shown in Fig 3. The SEM images show the distribution of the silica with average size particles ranging from 20 to 39 nm. These results show a fine dispersion of silica particles in the matrix and when the concentration of inorganic phase is increased. Nanocomposite films have a very homogeneous distribution with no preferential accumulation of silica in any region across the films. The micrographs also indicate the presence of interconnected silica domains in the continuous polyamide phase, which demonstrates better compatibility between smaller silica nanoparticles and the PAI in the nanocomposite films.

**Optical clarity of PAI-nanocomposite films**

Optical clarity of PAI-nanocomposite films containing 5-20 wt.% clay platelets and neat PAI was compared by UV-Vis spectroscopy in the region of 260-800 nm. Fig. 5 show the UV-Vis transmission spectra of pure PAI and PAI-nanocomposite films containing 5-20 wt.% clay platelets. These spectra show that the UV-Visible region (250-800 nm) is affected by the presence of the clay particles and exhibiting low transparency reflected to the primarily intercalated composites. Results shows that pure PAI and PAI-nanocomposite films various amounts of silica are transparent, and the transmittances recorded at 450, 500, 600, 700 and 800 nm for PAI and PAI-nanocomposite thickness were 81.52, 92.65, 96.88, 97.59 and 98.10 %, respectively Table 1. The maximum transmittance was found for the PAI (Table 1). The transparency of these nanocomposites depends upon the size and spatial distribution of silica particles in the PAI matrix. Nanocomposite films were transparent because the average size of the ceramic particles is smaller than the wavelength of light, and the distribution of particles is relatively uniform. Ultimately the tendency for the agglomeration of small particles into larger ones may increase, which decreases the homogeneity of the system. As particle size becomes larger, the transmittance values decrease.

**Thermal Properties**

The thermal properties of PAI-nanocomposite films containing 10 and 20 wt% clay platelets and neat PAI were were investigated by TGA in a nitrogen atmosphere at a heating rate of 10 K/min (Fig. 6).

Initial decomposition temperature, 5% and 10% weight loss temperatures (T5, T10) and char yields are summarized in Table 2.

These samples exhibited good resistance to thermal decomposition. T5 for neat PAI and PAI-nanocomposite films containing 10 and 20 Wt% clay platelets ranged at 210-350 °C.

\( a,b \) Temperature at which 5% or 10% weight loss was recorded TGA at a heating rate of 10 K/min in N\(_2\).

\( c \) Weight percentage of material left after TGA analysis at maximum temperature 800 \( \degree C \) in N\(_2\).

and \( T_{10} \) for them ranged from 260-395 \( \degree C \), and residual weights at 800 \( \degree C \) ranged from 49.65 to 56.22% in nitrogen respectively. Incorporation of organoclay into the PAI matrix also enhanced the thermal stability of the nanocomposites. Thus, we can speculate that interacting PAIs chains between the clay layers serve to improve the thermal stability of nanocomposites. The addition of organoclay in polymeric matrix can significantly improve the thermal stability of PAI.

**Water absorption measurements**

The results showed maximum water uptake for the pure polyamide (16.25%) with monotonic but asymptotic decrease thereafter (Table 2). The exposure of polar groups to the surface of polymer where water molecules develop secondary bond forces with these groups. The clay platelets obviously restrict the access of water to the hydrogen-bonding sites on the polymer chains. The weight gain by the films gradually decreased as the clay content was increased. It is apparently due to the mutual interaction between the organic and inorganic phases. This interaction resulted in the lesser availability of polar groups to interact with water. Secondly, the impermeable clay layers mandate a tortuous pathway for a permeant to transverse the nanocomposite. The enhanced barrier characteristics, chemical resistance and reduced solvent uptake PAI-nanocomposites all benefit from the hindered diffusion pathways through the nanocomposite [25].

**Conclusions**

The PAI-nanocomposites were successfully prepared using solution intercalation method. The structure and the uniform dispersion of organoclay throughout the PAI matrix were confirmed by FTIR, XRD and SEM analyses. The optical clarity and water absorption property of PAI-nanocomposites were decreased significantly with increasing the organoclay contents in PAI matrix. On the contrary the thermal stability of PAI-nanocomposites were increased significantly with increasing the organoclay contents in PAI matrix. The enhancements in the thermal stability of the nanocomposite films 5b and 5d caused by introducing organoclay may be due to the strong interactions between polymeric matrix and organoclay generating well intercalation and dispersion of clay platelets in the PAI matrix. Thermal and organosoluble properties can make these nanocomposites attractive for practical applications such as processable high-performance engineering plastics.

**Experimental Section**

**Materials**

Trimellitic anhydride, \( L \)-Alanine, 4,4’-diamino diphenyl ether, acetic acid, triphenyl phosphate (TPP), CaCl\(_2\), pyridine and \( \eta \)-methyl-2-pyrrolidone (NMP) were purchased from Merck Chemical Company and used without previous purification. Purified montmorillonite Cloisite\textsuperscript{®} Na\textsuperscript{+} and the organocally modified Cloisite\textsuperscript{®} 20A supplied by Southern Clay Products (TX), were used as polymer nanoreinforcement. The organic modifier and the interlayer distance of the clays are shown in Table 1 to account the structural modifications of the functionalizations.

**Measurements**

IR spectra were recorded on a Galaxy series FTIR 5000 spectrophotometer (England). Band intensities are assigned as weak (w), medium (m), strong (s) and band shapes as shoulder (sh), sharp (s) and broad (br). UV-Vis absorptions were recorded at 25 \( \degree C \) in the 190-700 nm spectral regions with a Perkin-Elmer Lambda 15 spectrophotometer on NMP solutions by using cell path lengths of 1 cm. \(^1\)HNMR spectra were recorded on a Bruker 300 MHz instrument (Germany). Inherent viscosity was measured by a standard procedure using a Technino\textsuperscript{®} viscometer. Thermal Gravimetric Analysis (TGA) data were taken on a Mettler TA4000 System under N\(_2\) atmosphere at a rate of 10 \( \degree C/min. \) The morphology of nanocomposite film was investigated on Cambridge S260 scanning electron microscope (SEM). Elemental analyses were performed by Vario EL equipment.

**Monomer Synthesis**

Synthesis of N-trimesellite-imido-L-Alanine. The diacid 3 was synthesized according to pervious work [26].

**Polymer Synthesis**

In a 100 mL round bottomed flask were placed a mixture of N-trimesellite-imido-L-alanine 3 (0.002 mol), 4,4'-diamino diphenyl ether 4 (0.002 mol), 0.60 g of calcium chloride, 1.2 mL of triphenyl phosphate, 1.0 mL of pyridine and 3.0 mL NMP. The mixture was heated for 1 h at 60 °C, 2 h at 90 °C and then refluxed at 130 °C for 8 h until a viscous solution was formed. Then it was cooled to room temperature and 40 mL of methanol was added to reaction mixture. The precipitate was formed, filtered off and washed with methanol. The resulting polymers 5 were dried under vacuum to leave 0.13 g (97%) of solid polymer. The inherent viscosity of this soluble PAI 5 was 0.64 dL/g. IR (KBr): 3414 (m, br), 3050 (m), 2900 (m), 1780 (w), 1715 (s, br), 1660 (s, br), 1600 (m), 1530 (s), 1500 (s), 1410 (m), 1380 (s), 1320 (m), 1220 (s, br), 1160 (m), 1100 (m), 1090 (m), 1010 (m), 950 (m), 890 (m), 860 (m), 830 (m), 760 (w), 727 (m), 500 (m, br) cm\(^{-1}\). Calcd. for C\(_2\)H\(_7\)N\(_3\)O\(_3\) (427): C, 67.0; H, 3.6; N, 9.5. Found: C, 67.4; H, 3.9; N, 9.8.

**PAI-Nanocomposite synthesis 5a-5d**

PAI-nanocomposites 5a-5d were produced by solution intercalation method, in four different amounts of organoclay particles (5-20 wt.%) increasing in 5 wt.% each) were mixed with appropriate amounts of PAI solution in N-methyl-2-pyrrolidone (NMP) to yield particular nanocomposite concentrations. To control the dispersibility of organoclay in polyamide-imide matrix, constant stirring was applied at 25 °C for 24 h. Nanocomposite films were cast by pouring the solutions for each concentration into Petri dishes placed on a leveled surface followed by the evaporation of solvent at 70 °C for 12 h. Films were dried at 80 °C under vacuum to a constant weight. Scheme 1 shows the flowchart diagram and synthetic scheme for PAI-nanocomposite films 5a, 5b, 5c, and 5d.

**The water absorption analysis**

The water absorption analysis of PAI-nanocomposite films was carried out using a procedure under ASTM D570-81 [27]. The films were dried in a vacuum oven at 80 °C to a constant weight and then weighed to get the initial weight (W\(_o\)). The dried films were immersed in deionized water at 25 °C. After 24 h, the films were removed from water and then they were quickly placed between sheets of filter paper to remove the excess water and films were weighed immediately. The films were again soaked in water. After another 24 h soaking period, the films were taken out, dried and weighed for any weight gain. This process was repeated again and again till the films almost attained the constant weight. The total soaking time was 168 h and the samples were weighed at regular 24 h time intervals to get the final weight (W\(_f\)). The percent increase in weight of the samples was calculated by using the formula (W\(_f\) - W\(_o\))/W\(_o\).
