ABSTRACT
Objective: The aim of this study was to identify the incidence of postural changes and temporomandibular disorders (TMD) in children and adolescents. Methods: We selected 117 individuals aged 10–18 years from a state school in the Zona da Mata region of Minas Gerais. The students were evaluated in four stages: assessment of body weight and height and calculation of body mass index; posture evaluation using a questionnaire developed by the researchers; application of a questionnaire recommended by the American Academy of Orofacial Pain to assess TMD; and, finally, application of the Fonseca anamnesis questionnaire. Results: Of our sample, 26.36% had no TMD, 50.9% had mild TMD, 21.8% moderate TMD, and 0.9% severe TMD. Of the participants with moderate or severe TMD (30.8%), about 56% had some kind of change in head positioning. We found that 88% of the children with moderate or severe TMD had changes in the shoulders. Conclusion: The postural changes found in the head and shoulders are related to the biomechanical adaptation of the muscles of mastication and consequent changes in the TMJ.

Keywords: Temporomandibular joint disorders. Physical therapy specialty. Therapy.

INTRODUCTION
The temporomandibular joint (TMJ) is a modified gliding joint composed of the condylar process, fossa of the mandible and articular tubercle of the temporal bone.¹⁻¹⁸ This joint allows the protrusion, elevation, retraction and lateral sliding movements of the mandible, which are mainly produced by mastication muscles: masseter, temporal and lateral and medial pterygoid.²⁻¹⁸ There are diseases that compromise TMJ and adjacent structures, constituting temporomandibular disorders (TMD), which are characterized by pain, joint sounds, chewing and speech impairments, irregular jaw function and even changes in global posture.³

A TMJ is directly related to the biomechanics of the cervical and scapular structures through a common neuromuscular system, being that postural alterations of the spine may entail to disturbances in the TMJ and vice versa. Body realignment may interfere with the function and organization of the joint. Just as it can be consequence of temporomandibular disorder.⁴ This relationship of reciprocity between body posture and TMD can establish a form of prevention and rehabilitation for patients.³
Studies show that about 40% of the world population has some type of TMD and several studies indicate what carriers with such dysfunction can undergo several changes in the positioning of the head and shoulders. In addition, it is verified in the literature there is a greater impairment of TMJ in women than in men, in a ratio of 4 to 1, respectively.\(^5\)

The etiology of TMD is related to muscular hyperactivity and this, in turn, has as its main cause the practice of parafunctional habits that is aggravated by emotional stress. The symptoms of TMD are: pain, headache, joint noise, besides changes in mandibular dynamics, restriction of movements and changes in muscle tone.\(^4\)

Individuals with TMD present an overload in the cervical muscles due to increased activity of the masticatory muscles to compensate for joint disorder.\(^6\) Such overloading may result in mandibular and spinal deviations, as well as cervical hyperlordosis, since there is shoulder elevation and head protrusion in patients with TMD. Thus, although the main complaint of TMD is the pain and limitation of the mandibular opening, this may be accompanied by muscle fatigue and alteration in the bone axis of the spine and, therefore, postural problems in the patient.\(^7\)

The objective of this article was to identify the incidence of postural changes and TMD in school children and adolescents in a medium-sized city in the forest area of Minas Gerais.

**METHODS**

Were selected 117 school-aged individuals aged 10 to 18 years old were selected from a state school of Minas Gerais. As inclusion criterion were school children and adolescents between the ages of 10 and 18, of both genders, who signed the term of free and informed consent and accepted to participate in the research. The exclusion criterion was children and adolescents who did not agree to participate in the study and did not sign the free and informed consent form.

All the participants were informed about the questionnaire to be answered, the TMD assessment, the postural evaluation and their responsible signed the consent form and free and informed consent at the time of admission to the research, according to Council Resolution 466/2004. The development of this research project was approved by the Ethics Committee of the Federal University of São João Del Rei / Santo Antônio Campus (protocol 017/2014). The evaluation of the students in the research followed four stages: in the first stage the body weight, height and calculation of Body Mass Index (BMI) were evaluated; in the second stage, a postural evaluation was performed, using a questionnaire prepared by the researchers. In the third stage, the questionnaire for the evaluation of TMD recommended by the American Academy of Orofacial Pain was applied, and in the fourth step the Fonseca anamnestic questionnaire was applied, being that Fonseca anamnestic questionnaire was applied only to the individuals who answered “yes” “On the questionnaire of the American Academy of Orofacial Pain. The postural changes were evaluated through the application of a postural evaluation sheet prepared by the researchers, being that and the same was done in a calm environment where the child or adolescent was evaluated in three positions: anterior, profile and posterior. The postural evaluation was performed with the supervision of a physiotherapist.

The American Academy of Orofacial Pain Questionnaire was used for an initial screening of potential TMD patients. This questionnaire presents ten TMD questions. The questions are simple questions that can be answered by the student, having as answer: yes or no.\(^10\)\(^-\)\(^17\)

The Fonseca anamnestic questionnaire was applied in the last phase and aims to characterize the severity of TMD.\(^11\)\(^-\)\(^19\) and is widely used in epidemiological studies. This questionnaire consists of ten simple questions, where each question has three possible answers (yes, no and sometimes), for which the scores are: 10, 5 and 0, respectively. The final sum of the questionnaire allows to classify the evaluated according to the severity of the symptoms: without TMD (0 to 15 points), mild TMD (20 to 45 points) and moderate TMD (50 to 65) and severe TMD (70 to 100 points).

**RESULTS**

The results showed that of the 110 individuals evaluated, the mean age was 13.9 years (10-18) and the mean BMI was 19.3 kg/cm. About 18 individuals were not evaluated by the Fonseca (NA) questionnaire because they answered “no” in all questions from the American Academy of Orofacial Pain Questionnaire. Among the total of the sample, about 10% of the individuals (n = 11) had no TMD, 50.9% (n = 57) had mild TMD, 21.8% (n = 24) had moderate TMD and 9.9% (n = 11) presented severe TMD, as shown in Figure 1. Of the 22.7% (n = 25) who had moderate or severe TMD, about 56% (n = 14) presented some type of head alteration and the other 44% (n = 11) presented no head position changes. Among the postural alterations evaluated in the head was observed that 12% presented head protrusion and 44% presented head tilt to the right or left. Among the patients with moderate or severe TMD, 22.7% (n = 25), 64% presented a shoulder elevation and 24% had a shoulder protrusion. Other postural alterations were observed in the studied population, and 67.27% (n = 74) had pelvic alterations, such as anteverision and pelvic retroversion, and 24.3% (n = 18) of these individuals were classified as having moderate and severe TMD. Other postural alterations were found, such as: cervical hyperlordosis, thoracic hyperkinesis, lumbar hyperlordosis and thoracolumbar scoliosis, with about 24.1% (n = 14) presenting moderate and severe TMD. In the knee, changes were identified as: valgus knee, varus knee and recurvatum knee in 26% (n = 13) of individuals with moderate and severe TMD.

**DISCUSSION**

Thus, a high incidence of postural changes and TMD can be observed in the studied population. The higher incidence of alterations in the cervical, head and shoulders region is related to the mechanism of biomechanical adaptation of chewing muscles in this region.\(^12\)\(^-\)\(^23\) DTM promotes compensatory mechanisms of the masticatory muscles that fixate in the region of the sternum and the scapula.\(^13\) This biomechanical adaptation pulls the shoulder superiorly or anteriorly, determining changes in the shoulders.\(^8\)

In the present study, no correlation was found between postural changes found in the spine, hip and lower limbs with the presence of TMD, but these alterations could trigger future problems in the study population. These changes may be related to the intrinsic

*Acta Ortop Bras. 2017;25(4):162-4*
and extrinsic factors of the child or adolescent.\textsuperscript{14} Studies show that there are genetic, ergonomic and lifestyle factors that may trigger these postural changes.\textsuperscript{15} With this, it becomes necessary to develop orientation programs and rehabilitation for these children and adolescents with the purpose of preventing future complications.\textsuperscript{16}

CONCLUSION

It was concluded that a high incidence of mild TMD and postural alterations occurred in the head, neck and shoulders region among the evaluated children and adolescents. There was no significant relationship between pelvic and knee changes, as well as BMI, and the occurrence of TMD. Thus, a program of prevention and orientation of these students is essential, aiming at reducing the incidence of postural changes and consequently TMD.

ACKNOWLEDGEMENTS

We thank the pedagogical team of the State School of a city of Minas Gerais, the school board and the teacher of Physical Education. In addition, we thank the students and parents who accepted the participation in the research.
